Abstract

Geomorphic features (fossil terraces, notches and sea cliffs) from the southern Red Sea coasts provide valuable indicators of past sea-level change that enable the quantification of both the timing and magnitude of the mid-Holocene sea-level highstand. We demonstrate the utility of wave-cut notches in the southern Red Sea, and present U-series dated sea-level indicators from two locations on the As-Salif Peninsula that suggest a mid-Holocene highstand of ~ 0.5 to 1 m above present mean sea level (apmsl) at about 5 to 5.4 ka BP. In addition, the similarity of the elevations of the different sea-level indicators at the two locations in As-Salif Peninsula and Kamran Island suggest relative tectonic stability, with limited influence of salt diapirism. Comparison of our data to other estimates of the Red Sea mid-Holocene highstand, and glacio-isostatic predictions suggest that water loading (and deformational response) is the primary factor in the spatial and temporal variability the mid-Holocene highstand, with some possible localized tectonic and neotectonic overprinting.

Key words:

Red Sea; mid-Holocene sea level; coastal geomorphology; fossil corals; wave-cut

notches; U-series dating

1. INTRODUCTION

Relatively little is known about the relative sea level (RSL) variations during the Holocene for large segments of the Red Sea coasts, especially the south of the basin (e.g., Edelman-Furstenberg et al., 2001; Lamy et al., 2006; Lambeck et al., 2011). Early studies assigned emerged sea-level indicators (e.g., coral terraces) along the Red Sea coast to sea-level fluctuations and tectonic processes only, and ignored contributions from the glacio-isostatic adjustment (GIA) and water loading processes (e.g., Al-Rifaiy and Cherif, 1988; Gvirtzman et al., 1992; El-Asmar, 1997; Strasser and Strohmenger, 1997; Shaked et al., 2002). As GIA affects not just near-field regions (i.e., those located close to the former ice sheets) but also the intermediate and locations such as the Red Sea (Mitrovica and Peltier, 1991; Peltier, 1999; Milne and Mitrovica, 2008; Lambeck et al., 2014), considerable spatial variability in amplitude, magnitude and timing of highstands in the Red Sea is expected and predicted from GIA modelling (Lambeck et al., 2011).

Tectonically, the Red Sea is not stable and geologic, geodetic and seismic evidence indicates pronounced vertical movements across the Red Sea basin throughout the latest rifting phase that started in the Miocene (Girdler and Styles, 1974; Hötzl, 1984; Hempton, 1987; Purser and Bosence, 1998). In addition, vertical movement associated salt diapirism occurs in some parts of the Red Sea, such as the As-Salif Peninsula (Figure 1) and these vertical movements have influenced the carbonate reef deposits, often resulting in irregular uplift of the terraces.

As indicators of local sea level form as a result of the interplay between eustatic sea-level change, tectonic uplift or downwarping, and GIA processes, we expect the combined imprint of each of these processes to be preserved at the stratigraphic record of the Red Sea. In this study we utilize wave-cut notches from the southern Red Sea, Kamaran Island and the As-Salif Peninsula, to provide information on both local tectonic history and past sea level. We provide mid-Holocene coral U-series ages for the Yemeni Red Sea coast and document geomorphic features on As-Salif

Peninsula and Kamaran Island coasts. We take advantage of the varied geologic/ neotectonic setting of the area to: (i) investigate the potential of wave-cut notches as a palaeo tide and sea-level indicators in the Red Sea; (ii) provide sea-level constraints to test the GIA predictions of Red Sea sea levels during the Holocene; and (iii) interpret the tectonic history of the complex, faulted region in the southern Red Sea.

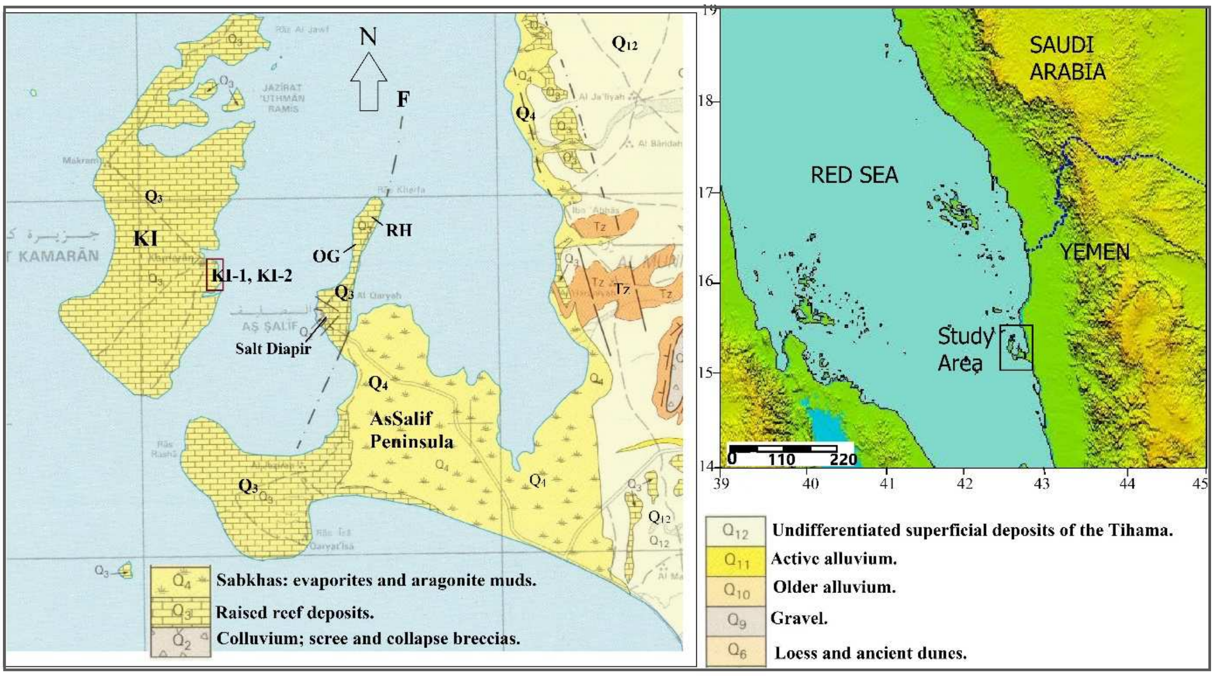

Figure 1: Topographic map of Yemeni Red Sea showing Kamaran and As-Salif Peninsula and the study/sampling locations (OM = Om Gedi; RH = Ras Harafa; KI-1 and KI-2 are the two sampling locations on Kamaran Island).

2. LOCATION, GEOMORPHOLOGY AND STRATIGRAPHY

2.1 Tidal regime and coastal setting

The Red Sea is characterized by a semi-diurnal microtidal regime, with the tidal range increasing with distance from the centre of the basin, from virtually no daily change to about 0.6 m in the north and up to 0.9 m in the south (at Massawa and Kamaran Island) (Edwards, 1987). The tidal range results from the interaction of tides produced in the Red Sea itself and the co-oscillation with the Indian Ocean (Defant, 1961). The latter is attenuated by the narrow Bab al Mandeb Strait resulting in generally low tidal amplitudes in the Red Sea. The effect of the strait can be seen from increasing tidal amplitudes northwards, with the highest tidal range recorded in Kamaran Island of ~ 1 m.

The wave regime (direction, wave height) at the study sites is driven by three principal seasonal wind systems operating in the Red Sea, and waves tend to propagate along the axis of the Red Sea basin (Clifford et al., 1997; Sofianose, 2003; Langodan et al., 2017). Significant wave height varies seasonally with the monsoon reversal (Ralston et al., 2013; Langodan et al., 2018); during the winter, monsoon winds from the southeast generate waves with mean significant wave heights in excess of 2 m and mean periods of 8 s in the southern Red Sea, with lower wave heights during the summer (Ralston et al., 2013). The indented coasts of the Red Sea leads to a reduction in swell, especially in the southern zone (Langodan et al., 2017).

2.2 As-Salif Peninsula

The As-Salif Peninsula is part of the ~40 km wide, N-S trending, Tihama coastal plain (Davison et al., 1994) (Figure1). The southern Red Sea, including islands and volcanic coastal formations, are associated with the main Red Sea Rift and Afar rift, which are parallel to the coast and have numerous fault lines (Rowlands and Purkis, 2015). An irregular distribution of carbonate bodies occurs as a result of local faults, differential uplift due to salt diapirs, and variable erosion/depositional processes (Bosence, 2005; Purkis et al., 2012; Rowlands and Purkis, 2015). Tectonically, the As-Salif Peninsula is an intensely deformed area, with vertical bedding and steeply plunging isoclinal folds (Davison el al., 1996).

The geomorphology of Red Sea makes it conducive to evaporite and salt diapir formation (Bosworth, 2015) with mid- to late Miocene salt deposits (16.4-5.3 Ma) forming shortly after Red Sea basin rifting terminated (Heaton et al., 1996; Davison et al., 1996). The vast desert and arid climate of the region also create the conditions for salt diapirs to form and develop into domes and islands (Bosence, 2005). The evaporites in this region are sandwiched between Pliocene siliciclastics sediments beneath, and Pleistocene and Holocene carbonates above (Brown, 1970; Mitchell et al., 1992; Bosence et al., 1998). The stress exerted by the rocks above, force the evaporites to elevate the overlaying strata to create diapiric structures (Purser and Bosence, 1998; Bosence et al., 1998; Gracia et al., 2008).

The As-Salif Peninsula is produced by a linear north-south trending salt diapir, bounded by a normal growth fault on the eastern margin, and this diapiric wall continues offshore for several kilometres (Bosence et al., 1998). Boreholes drilled in the region show that evaporite influence is unevenly distributed beneath the coastal shelf, and the thickest evaporites are found offshore (Bosence et al., 1998; Rowlands et al., 2014). The domed morphology of As-Salif diapir is topped by corals dominated by *Galaxea fascicularis*, particularly in the lower sections of the fossil reefs, with more diverse coral assemblage in the upper section of the reefs (Bosence, 2005; Purkis and Riegl, 2012) (Figure 2).

In brief, the Salif Formation in the region comprises a thick halite, disconformably overlain by bedded gypsum with thin layers of carbonate (the Ghawwas Member), capped by about 5 m of gypsiferous/calcareous clastics. The Salif Formation is intermittently exposed along the coastal region of the Tihamah plain of the Yemeni Red Sea and we selected two emergent terraces for further investigation. These comprise two low lying, flat-topped emergent terraces in the northern As-Salif Peninsula, Om Gedi and Ras Harafa (Figure 1). A normal fault, which is oriented parallel to salt diapir faults, passes through the northernmost As-Salif Peninsula, and may be responsible for the emergence of these terraces (Rowlands and Purkis, 2015).

The Om Gedi terrace (OG) (upper Salif Formation), is formed predominantly of coarse to fine grained siliciclastic lithology impregnated with gypsiferous/anhydrite beds (Figure 3). Such deposits are typically a result of sabkha cycles, where alternating episodes of sea water saturation and flushing with meteoric water in intertidal sediments lead to gypsum formation (Wright, 1994). The high content of siliciclastic grains suggests deposition by wind (Youssef, 1991).

The Ras Harafa terrace (RH) is largely formed of gypsum and gypsiferous clastics intercalated with detrital material (also upper Salif Formation) (El-Nakhal and Alaug, 2013; Beydoun et al., 1998), with a series of cliffs, notches, and caves on its seaward face. Recent gypsum deposits encrust coral reef fragments atop a wave-cut platform below to marine terrace (Figure 4). The shape and location of the As-Salif Peninsula terraces suggests a primary tectonic control on their spatial distribution.

2.3. Kamaran Island

Kamaran Island (KI) is located in shallow waters of north-eastern part of Yemeni Red Sea and separated from the eastern coast by a narrow strait known as As-Salif strait (Figure 1). The island is a post-rift sequence formed of carbonate deposits that developed on the eroded uppermost layer of the Plio-Pleistocene platform (Angelucci, 1981; Angelucci et al., 1985). These carbonate deposits (reefal limestones, ca. 1.81 - 0.01 Ma) represent the uppermost 10 m of a shallow water sedimentary complex that overlies an evaporite sequence of Miocene age (Davison et al., 1996; Bosence et al., 1998).

A sequence of notches, cliffs, and platforms is evident in the carbonate rocks of Kamaran Island. These were incised through tidal and/or wave action and can be used as a palaeo-sea level indicators, although debate as to the exact processes governing formation continues (e.g., Pirazzoli, 1986; Rust and Kershaw, 2000; Kershaw and Guo, 2001; Kelletat, 2005; Evelpidou et al., 2012; Moses, 2013). Recent sediments comprise mostly of fossil remains (e.g., corals, molluscs, calcareous algae, and benthic foraminifera) and reworked materials from the nearby rocks.

3. MATERIALS AND METHODS

We mapped the geomorphic features (wave-cut notches, cliffs etc.) at each site; elevations were determined using either direct measurement by levelling and/or differential Global Positioning System (GPS) measurements and are reported relative to present mean sea level (above present mean sea level, apmsl). The uncertainty in the GPS elevation measurement is ± 2 cm, with greater uncertainty associated with our levelling (we use a conservative estimate of 20 %). The inflection points of wave-cut notches indicates the position of mean sea level at the time of formation (Antonioli et al., 2015). However, we had difficulty in determining the vertex at our sites, as most of the notches are of U-shape and/or obscured by sediment. As such, we report the approximate elevation of the inflection point through comparison with analogue modern notches. The total elevation error was calculated by summing all the contributing sources of error in quadrature (Table 1).

We collected *in situ Porites* sp. and *Acropora* sp. corals (i.e., the corals were found upright in growth position, with no indication of later displacement) for U-series dating. We assume corals from the fossil reef platform immediately below the wave-cut notches lived at the time as when the notch was cut (cf. Rovere et al., 2015; Lorscheid et al., 2017). Modern corals in the area are intertidal. Twelve coral samples were collected (Table 1): 6 samples from two locations in Kamran Island (KI01 and KI02) (at +4 ± 1 m apmsl), two *in situ* corals from a patch reef on top of the As-Salif diapirs (+18 ± 2 m apmsl); two *in situ* corals from the Om Gedi (OG) (+1 ± 0.2 m apmsl) and; two corals *in growth* position from Ras Harafa (RH) (+ 0.5 ± 0.2 m apmsl) (Figure 1).

Corals selected for radiometric dating were initially examined petrographically and by X-ray diffraction to ensure that corals were primary aragonite. The XRD determinations were carried out using Rigaku Miniflex XRD, with JADE 7 software (Connolly, 2010) used for peak identification. All corals collected from the As-Salif peninsula terraces are pristine (i.e., < 2 % calcite), whereas the coral samples from Kamaran Island were diagenetically altered (i.e., recrystallized) and only two samples from Kamaran Islands with the least amount of alteration (visual appearance and % calcite) were U-series dated. Samples that passed the initial XRD screening were lightly crushed and any discoloured material and/or debris was removed using a binocular microscope. Coral samples were then quarried out into cubes followed by multiple ultrasonic baths in distilled water, and dried at 30°C. The chemical procedures for the separation of U and Th from the sample are based on methods of Edwards et al. (1987). Approximately 0.2 - 0.3 g of ultrasonically cleaned samples were weighed and spiked with a mixed ^{229}Th-^{233}U-^{236}U tracer. Uranium and thorium were separated with iron co-precipitation and anion-exchange chromatography. The uranium and thorium aliquots were dissolved in 1% HNO_3 + 0.005N HF for instrumental measurements (Shen et al., 2002). Samples were subsequently analyzed by Neptune multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS) and a Faraday-multiplier following the procedure developed by Edwards et al. (1987, 1988); Cheng et al. (2008) and Shen et al. (2002). Ages were calculated using a half-life for ^{230}Th of 75,690 years and a half-life for ^{234}U of 245,250 years (Cheng et al., 2013). The age was solved for iteratively using the standard age equation presented in Edwards et al. (1987), using decay constants of 1.55125 x10^{-10} for λ_{238} (Jaffey et al., 1971), 2.82206 x 10^{-6} for λ_{234} (Cheng et al., 2013), and 9.1705 x10^{-6} for λ_{230} (Cheng et al., 2013). In addition, samples were corrected for initial non-radiogenic thorium using a $^{230}Th/^{232}Th$ atomic ratio of 4.4 ± 2.2 x10^{-6}.

4. RESULTS

4.1 U-series dating

Five *in situ* coral samples were collected from As-Salif Peninsula (two from the top of As-Salif Salt diapir, two from Ras Harafa (RH), and one from Om Gedi (OG). The measured ^{238}U concentrations of our samples varies between 1.14 and 2.61 ppm (Table 1). Samples from RH have ^{238}U concentrations consistent to modern pristine corals of living/dead corals from Bab al-Mandab (Al-Mikhlafi et al., 2018), and modern corals from Red Sea (Friedman, 1968; Gvirtzman et al., 1973). However, Holocene corals from the Om Gedi and As-Salif salt diapir have lower ^{238}U concentrations (Table 1), suggesting that these corals may have experienced secondary elemental or isotopic disturbance (cf. Yu and Zhao, 2010). The concentration of ^{232}Th in our samples varies from 0.375 ± 0.009 to 1.59 ± 0.033 ppb, the latter is significantly above the 0.5 ppb of pristine corals from oceanic islands and likely reflects the incorporation of detrital material into the corals (Edwards et al., 1987; Chen et al., 1991; Yokoyama et al., 2001). The modern value of $\delta^{234}U_i$ is widely used to detect digenetic alteration of fossil corals (e.g., Bard et al., 1991; Hamelin et al., 1991; Gallup et al., 1994) and all samples except those from Kamaran Island have calculated $\delta^{234}U_i$ values that are similar to the modern seawater value (146.8 ± 1 ‰, Andersen et al., 2010).

Table 1. U-series data of samples from Kamaran Island and As-Salif peninsula, southern Red Sea. All uncertainties are reported at the 2 sigma uncertainty level.

U decay constants: $l_{238} = 1.55125x10^{-10}$ (Jaffey et al., 1971) and $l_{234} = 2.82206x10^{-6}$ (Cheng et al., 2013). Th decay constant: $l_{230} = 9.1705x10^{-6}$ (Cheng et al., 2013).
*$d^{234}U = ([^{234}U/^{238}U]_{activity} - 1)x1000$. ** $d^{234}U_{initial}$ was calculated based on ^{230}Th age (T), i.e., $d^{234}U_{initial} = d^{234}U_{measured} \times e^{l234xT}$.
Corrected ^{230}Th ages assume the initial $^{230}Th/^{232}Th$ atomic ratio of 4.4 ±2.2 x10^{-6}. Those are the values for a material at secular equilibrium, with the bulk earth $^{232}Th/^{238}U$ value of 3.8.
The errors are arbitrarily assumed to be 50%
***B.P. stands for "Before Present" where the "Present" is defined as the year 1950 A.D.
The tidal range in Kamaran Island is ~1 m, and datum is taken as 0.5 m.
§ living corals.

All samples (except Kamaran Island) are mid-Holocene in age (after correction for detrital thorium, Table 1); samples from the top of the As-Salif salt diapir (SL01 and SL02) are dated to 7,616 ± 26 and 7,648 ± 38 years BP; Ras Harafa samples (RH01 and RH02) have ages of 5,423 ± 47 and 5,324 ± 25 years BP; and the Om Gedi coral sample was dated to 4,950 ± 30 years BP. The two fossil corals collected from Kamaran terraces were diagenetically altered with almost complete transformation from pristine aragonite skeleton into calcite. These samples yielded ages of 226,422 ± 1,871 years and 221,703 ± 2,533 years BP, although the dates obtained are unlikely to reflect the 'true' age of these samples due to the significant diagenetic alteration.

4.2 Reef and notch morphology

4.2.1 Al-Salif Peninsular salt diapir

Patch corals were found at altitude of +18 ± 2 m (apmsl) atop of As-Salif salt diapir (Figure 2) and two coral samples (*Porites* sp.) yielded mean (inverse weighted) age of 7,629 ± 31 years BP (Table 1). These samples were dated to confirm the Holocene age of this reef and investigate local deformation due to salt diapirism. Although these samples passed initial XRD screening (i.e., calcite content of < 2%), further investigation suggests U-depletion in both samples (SL01 and SL02). Further, sample SL02 has elevated ^{232}Th concentration compared to modern equivalents indicative of detrital input (see section 5.1 for further discussion of the age of these samples).

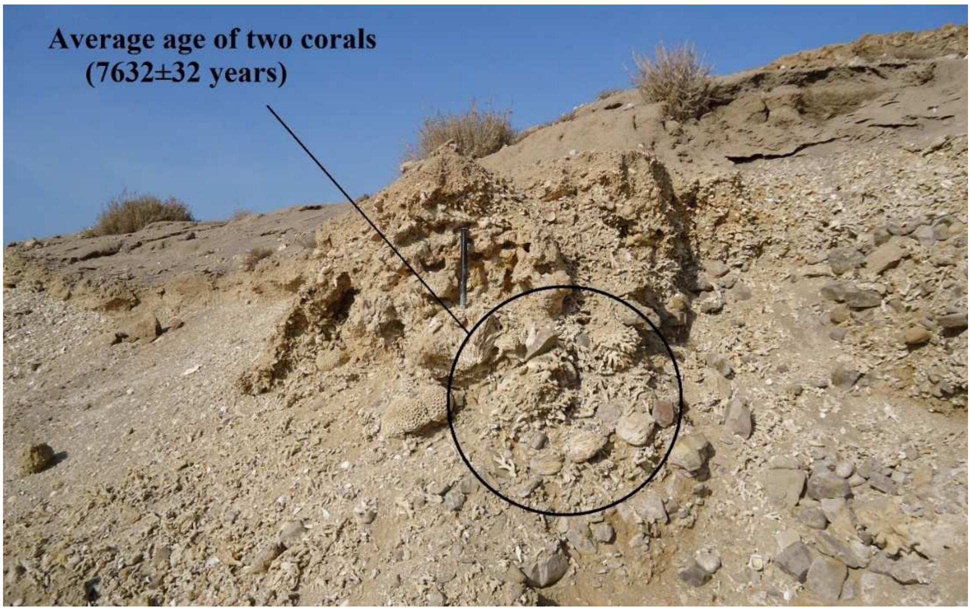

Figure 2: Coral samples (SL01 and SL02, circled) from the As-Salif salt diapir.

4.1.2 Om Gedi terrace (OG)

The OG terrace has a maximum mapped elevation of + 4 ± 1 m apmsl. It comprises an indurated aeolian (continental source) deposit, overlain by gypsiferous layer. Inspection of the OG terrace siliciclastic beach rocks indicate deposition in relatively quiet, subaerial and oxygen rich environment (fine grains and yellowish staining of the indurated sediments). The lack of reef corals at this site (i.e., the reefal limestone that overlies the Salif Formation elsewhere on the Kamaran and As-Salif Peninsula) may be due to very high terrestrial inputs and turbid-water environment that is unfavorable for large-scale carbonate production (Purser et al., 1987). A wave-cut notch mapped at +3 ± 1 m apmsl (Figure 3) and is assumed to be of Last Interglacial (LIg) age. We were unable to obtain reliable date for this feature but have assign a Last Interglacial age given the proximity and similarity in elevation to the U-series dated fossil reef at Bab al-Mandab, southern Red Sea (4±1 m apmsl; Al-Mikhlafi et al., 2018). This notch has its middle and upper portions preserved as notch roof, whereas its base buried under the aeolinite sand. A Holocene cliff developed below the LIg notch at an elevation of ~+1.5 m (Figure 3). An *in situ Porites* sp. coral (OG1; +1 ± 0.2 m apmsl), found intercalated with siliciclastic deposits adjacent to the Holocene wave-cut cliff, was dated to 4,950 ± 30 years BP (Table 1), and considered equivalent in age to cliff formation (Figure 3). The shape of Holocene cliff suggests that the cliff developed initially in the cohesionless aeolinite material and that the roof collapsed, likely due to wave action.

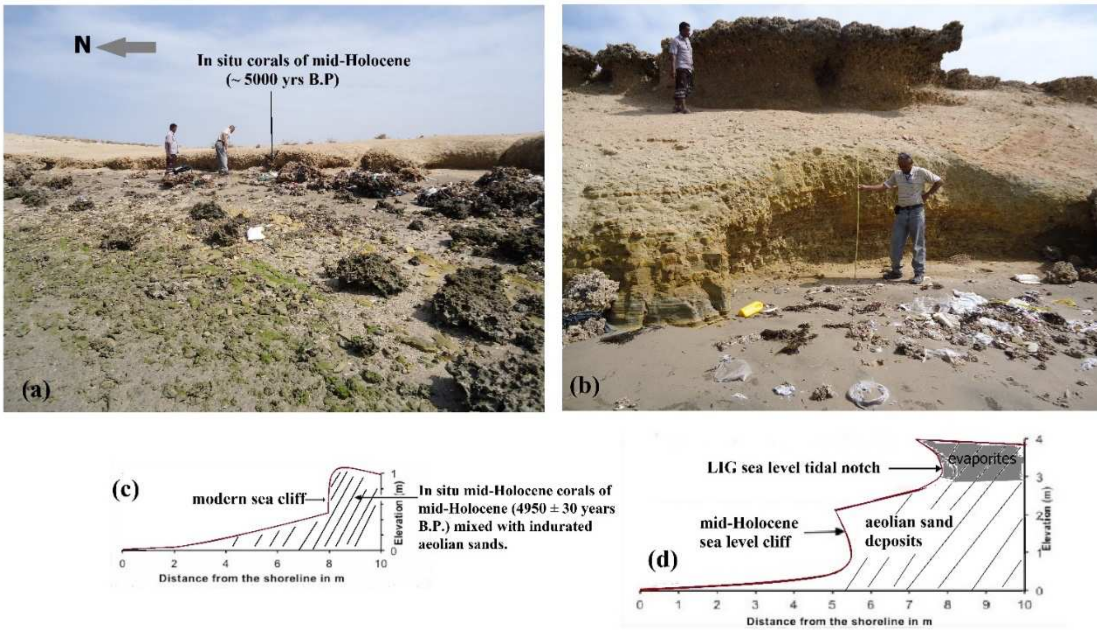

Figure 3: Photographs and field sketches of the Om Gedi terrace, As-Salif Peninsula. (a) An outcrop of *in situ Acropora* sp. of mid-Holocene age capped by siliciclastic sediments; and in the foreground, reworked boulder of gypsiferous sandstone from the main terrace (b) Photograph of mapped stratigraphic sequence showing mid-Holocene abrasion notch, with overlying LIg notch; (c) cross-section of (a) and; (d) cross-sections of (b).

4.1.3 Ras Harafa (RH)

RH is the northernmost terrace of As-Salif peninsula, and is the uppermost part of the Salif Formation. It has a maximum elevation of +3 ± 1 m apmsl. The terrace is formed of gypsum/gypsiferous clastics intercalated with fine grained siliciclastic material, with gypsum deposits (likely sabkha). Again, the reef limestones that typically overlie the Salif Formation are not represented here. Notches and solutional caves (Figure 4b), which can indicate the position of sea level at the time of their formation (Mylroie and Carew, 1988; Florea et al., 2007), are cut into the late-Miocene terrace (Figure 4c). Patch corals of Holocene age (RH01 and RH02; both +0.5 ± 0.1 m apmsl, Table 1) were found in a modern lagoon setting below the RH terrace at elevation of ~ 0.5 m apmsl. Recent gypsum deposits with mushroom/stromatolites morphologies are found encrusting mid-Holocene patch corals and are emerged during low tide (Figure 4a).

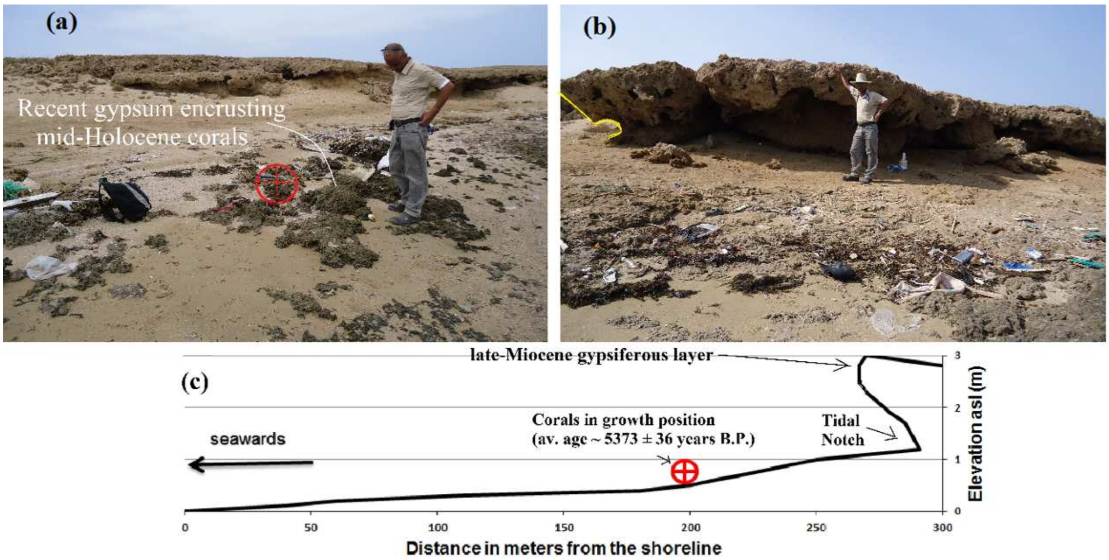

Figure 4: The Ras Harafa terrace, As-Salif Peninsula. (a) photograph of Holocene corals (foreground) with samples RH01 and RH02 highlighted in red. Assumed late-Miocene age terrace in the background; (b) notches/solution caves cut into late-Miocene terrace; (c) schematic cross-section of the Ras Harafa terrace.

4.1.4 Kamaran Island (KI)

The Kamaran Limestone is capped with a compact and highly weathered reef carbonate of early Pleistocene age, and contains variety of well-developed notches, and cliff structures. The area is microtidal and has generally sheltered coastal sites making the area promising for sea-level reconstruction.

In the north of the island, we documented distinct asymmetrical V-shaped notches with inflection points of 0.5 ± 0.2 m apmsl (Figure 5). The eastern part of Kamaran

Island is influenced by localized (neotectonic) vertical movement of the salt diapir intrusion, with clear displacement in the elevation of surveyed geomorphic features (reverse fault evident in Figure 6a). Five sites in this location were mapped in detail. At the first site, an embryonic notch (i.e., modern) is forming at close to present sea level in the Holocene cliff (maximum elevation ~ 1 ± 0.2 m apmsl) (Figure 6b, see also map in the *Supplementary Information doi: 10.6084/m9.figshare.13079240*). At the second location (slightly to the north), a series of notches was mapped, with 4 notches at elevations ranging from approximately +4 m to +2 apmsl (Figure 7a and b). This 'staircase' morphology (i.e., vertical separation of the notches) and U-shaped geometry (i.e., widening and deepening) of these notches likely resulted from vertical motion associated with coseismic uplift associated with the As Salif salt diapir (cf. Schneiderwind et al., 2017).
Progressing further around the bay to the north, a well-developed U-shaped notch of assumed LIg period is found at elevation of ~3 ± 1 m apmsl in weathered marly limestone (Figure 8a) and a V-shaped notch is well defined at +0.5 ± 0.2 m apmsl. Neither of these notches were dated but based on their elevation and comparison with other sites in the region, we assign the upper to the LIg and the lower to the mid-Holocene. *Lithophaga* boreholes in the lower unit may suggest slow uplift subsequent to the LIg period.

Finally, a well-developed, symmetric V-shaped wave-cut notch was observed in the uppermost section of the terrace, and corals at ~ +3 ± 1 m apmsl were selected for dating to corroborate our assumption of LIg age for notches cut at the elevation at this site (Figure 8b). Unfortunately, these corals were all highly diagenetically altered (corals KI01and KI02, Table 1) and yielded ages of >200,000 years BP (Table 1).

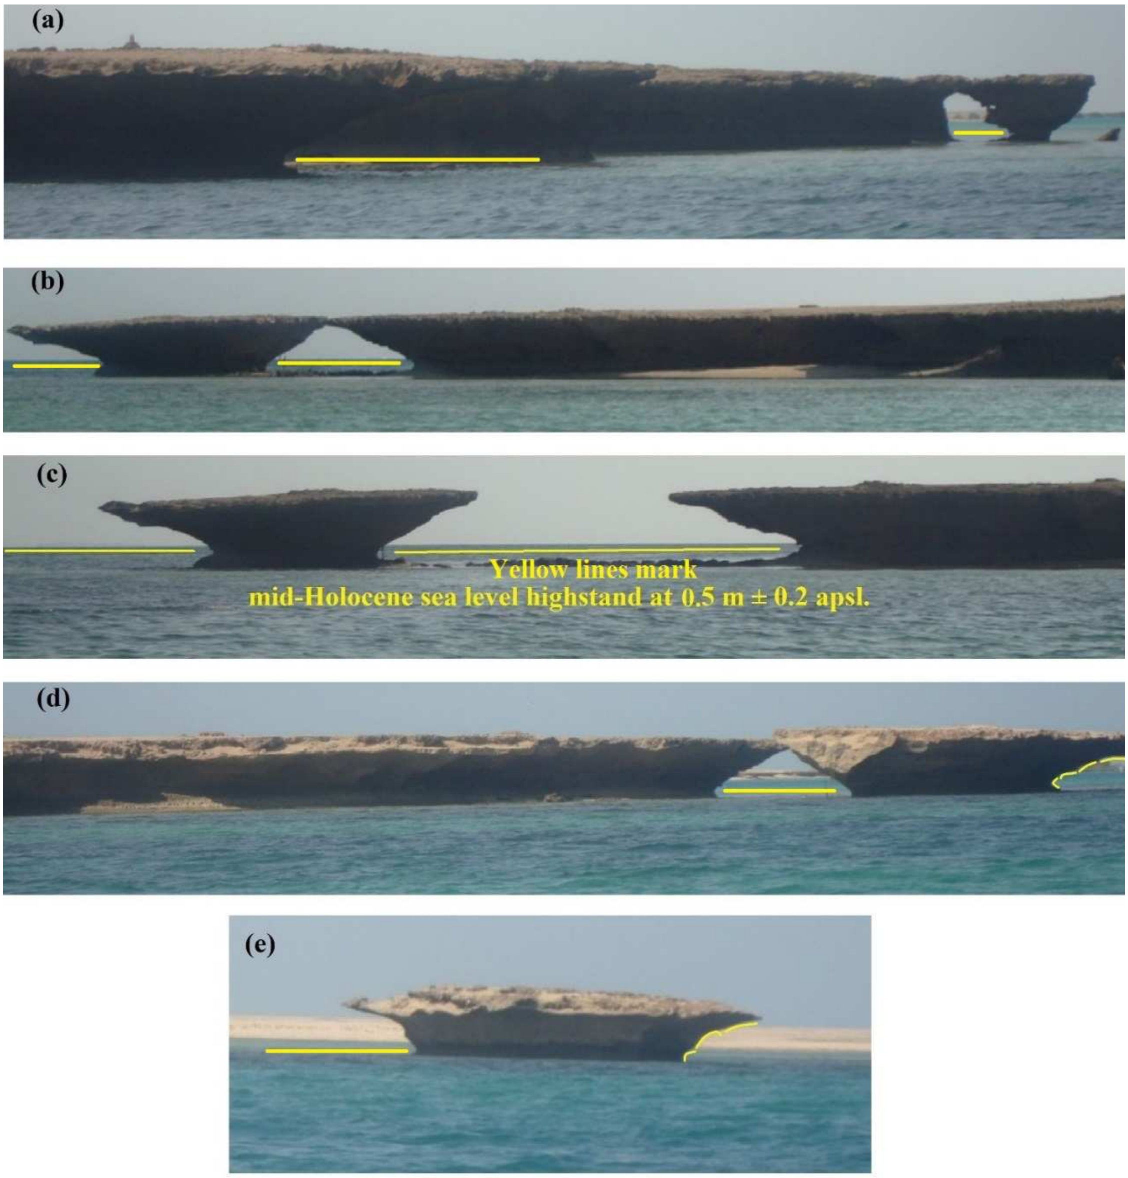

Figure 5: Wave-cut notches from the northern Kamaran Island, southern Red Sea. (a), and (b) were formed by wave action on a headland; (c), (d) and (e) sea stacks ("mushroom rocks") with well-developed marine notches just above present sea-level, and clear indentation at 0.5 m ± 0.2 apmsl.

5. DISCUSSION

5.1 Reliability of U-series geochemical data

All samples from this study show measured ($^{234}U/^{238}U)_{act}$ close to the modern sea water value of ~1.147 (Stirling and Andersen, 2009), and plot on or near the seawater evolution curve. All samples, except for those from RH, have ^{238}U and ^{232}Th concentrations that deviate from the live/dead corals of Bab al-Mandab (Al-Mikhlafi et al., 2018), modern corals from Aqaba (Scholz et al., 2004), and in the minimum range of ^{238}U concentrations of modern corals from Red Sea (~ 1.3 - 4.2 ppm) (Hibbert et al., 2016, and references therein) (Table 1). Plotting ^{238}U concentrations versus ($^{230}Th/^{238}U$) activity ratios (Figure 9a) provides insights into the effect of uranium loss on the apparent ages, due to the inverse relationships between ^{238}U concentrations and ($^{230}Th/^{238}U$) activity. Similarly, plotting ^{232}Th concentrations versus ($^{230}Th/^{238}U$) activity ratio, suggest that the effect of any uranium loss was accompanied by thorium addition (Figure 9b). These changes probably resulted from post depositional uranium loss, moving the data to the right on the diagram without affecting ($^{234}U/^{238}U$) activity (Figure 9c).

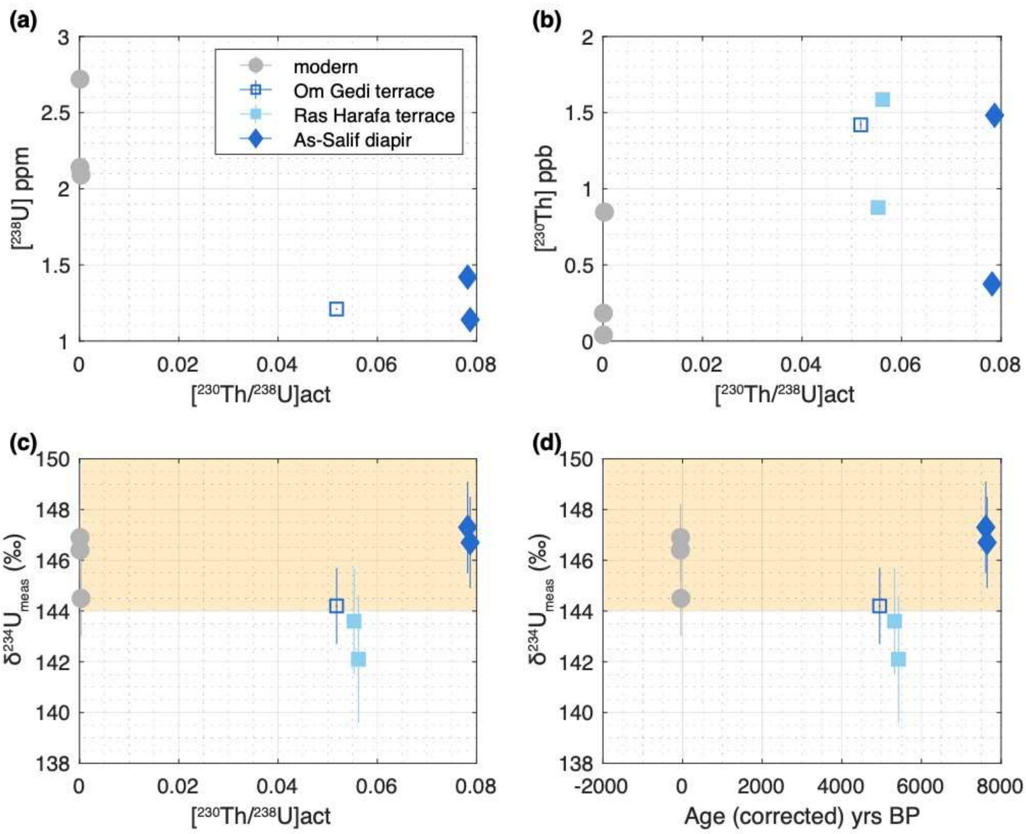

Figure 9: Bivariate plots of (**a**) ^{238}U concentration vs. $(^{230}Th/^{238}U)_{act}$ of samples from As-Salif Peninsula (note, errors are smaller than the symbols); (**b**) ^{230}Th concentration vs. $(^{230}Th/^{238}U)_{act}$ of the same samples (note, errors are smaller than the symbols); (**c**) Plot of $(\delta^{234}U)_{meas}$ vs. $(^{230}Th/^{238}U)_{act.}$ (**d**) $(\delta^{234}U)_{meas}$ vs. age of samples from the As-Salif Peninsula. The pale orange boxes represents the 'strictly reliable' values of $\delta^{234}U$ for modern seawater ($\delta^{234}U_{initial}$ = 147 ± 3 ‰). Errors are plotted at 2 sigma.

The corals from the top of the As-Salif salt diapir yielded mean U-series ages of ~7,630 years BP. These ages are in contrast to conventional radiocarbon dates of *Tridacna* shells by Davison et al. (1996) (reported as conventional radiocarbon ages of 3,700 ± 250 and 3,850 ± 250 years) from the same site and elevation. Our samples have lower ^{238}U concentrations than typical dead/live corals (2-3 ppm) and one, SL02, also has high ^{232}Th content (i.e., above the 0.5 ppb value for pristine coral samples), which may indicate the presence of secondary contamination. Both ^{238}U

loss and ^{232}Th high would increase the age and account for the offset with the radiocarbon ages of the *Tridacna* shells.

5.2 Notches as sea-level indicators in the southern Red Sea

Abrasion by wave and currents can create permanent wave-cut notches that, if preserved, can be useful palaeo sea-level indicators. Notches manifest as indentations or undercuts of a few centimetres to several meters (Antonioli et al., 2017) and form at or near mean sea level, during (a) prolonged stand-stills, and/or (b) when the rates of erosional processes are in line with the pace of relative sea-level change (Antonioli et al., 2006; Evelpidou et al., 2012). They are formed via chemical dissolution processes, wetting and drying cycles, biological erosion, wave action, or more likely, a combination of these factors (Antonioli et al., 2015). Often their vertical extension almost equals the tidal range (e.g. Pirazzoli, 1986). As a result, notches can serve as accurate sea-level indicators, especially in tectonically-stable regions (Neumann and Hearty, 1996; Antonioli et al., 2006; Hearty et al., 2007; Rodríguez-Vidal et al., 2007). However, in tectonically stable settings, wave-cut notches that were created in the late Pleistocene can be reoccupied and modified in the late-Holocene by sea level and associated wave action that reach similar elevations (Phillips, 1970; Trenhaile, 1972; Kelsey, 1990; Kelsey and Bockheim, 1994). Notches can also form from other (often interrelated) processes including eustatic/isostatic sea-level adjustments, tectonic and seismic processes (Carobene, 2015), as well as the action of chemical, physical, and biological factors (Pirazzoli, 1986, Antonioli et al., 2015).

A major limitation of using wave-cut notches as sea-level indicators is the difficulty in directly dating their formation. The dating of organisms that form the biological rim covering part of the notch (Pirazzoli et al., 1994a; Pirazzoli et al., 1994b; Faivre et al., 2013) or correlating the elevation of a notch with other datable markers has proved fruitful. An alternative approach, which we adopt here, assumes dates from corals found on the platform immediately below the notch are coeval with notch formation (Lorscheid et al., 2017). Unfortunately, we were unable to obtain ages for the older notches (elevation ~3 to + 4 m apmsl) as the corals showed significant diagenetic alteration and were unsuitable for dating. We therefore assume all notches at approximately +4 m apmsl that directly overlie the mid-Holocene notches, date to the LIg.

For the sites investigated, we found that some terraces are better preserved and less eroded than others, and this is mainly dependent on the rock lithology and hydraulic regime at each site. Sheltered beaches are more likely to develop notches than beaches with aggressive hydraulic regime. We attribute the differences in preservation/morphology of the features mainly to variation in tectonic activity of the region, resistance of the rock, the time the rocks were exposed to wave attack, and the variable occurrence of structural discontinuities such as cracks, fissures, joints, bedding planes, and faults (cf. Lorscheid et al., 2017). Variations in morphology (height, depth and shape) of the modern and fossil notches may also arise if the rate of erosion is not gradual and continuous (cf. Pirazzoli and Evelpidou, 2013), or from exposure to sub-aerial weathering by coseismic activity (Stiros et al., 2009, Pedoja et al., 2014).

At the tectonically stable Ras Harafa (RH) site, the sea cliff has a pronounced cave/large notch at + 2 ± 1 m apmsl (inferred LIg age) which may have been reoccupied during the late Holocene (Figure 10). This may suggest negligible GIA-induced net relative sea-level change from one highstand to the next (LIg and Holocene) and/or limited influence of tectonics, including salt diapirism in the area.

Figure 10: Photograph of the Ras Harafa terrace with LIg notch/cave at ~+2 ± 1 m apmsl; the yellow line is the highest tidal range.

In contrast, the preserved notch and sea cliff cut into the OG terrace, which is located closer to the As-Salif salt diapir, are distinctly separated in elevation (notches at ~+3 ± 1 m of inferred LIg age, and a mid-Holocene sea cliff at +1±0.2 m) (Figure 3b), with differences in host rock lithology having a strong control on their morphology. The LIg notch is carved into evaporite rocks, whereas the modern sea cliff is cut into poorly cemented recent aeolinite sand deposits. The LIg notch has additional structure, with middle and upper notch roofs preserved. The notch floor, however, is buried under aeolinite sand deposit making it difficult to measure the notch height, but this is clearly greater than the maximum modern tidal range. This could be a consequence of greater tidal range during the LIg, or a sequence of stillstands. The late Holocene sea cliff developed at the toe of LIg notch and probably formed as the result of abrasion processes where sediment entrained in waves or in turbulent broken wave bore, rushes up the beach face, excavating a “basal notch” and leaving the overhanging cliff material undermined, leading to failure (Bird, 2000). This process is promoted by the presence of groundwater in the cliff material (May and Heeps, 1985) and bioerosion (Trenhaile, 1987).

On Kamaran Island, a series of geomorphic structures - fossil coral terraces, wave cut platform, notches, and sea cliffs (Figure 6) – record past sea-level changes. A Holocene sea cliff is cut into indurated Pleistocene carbonate rocks at elevation of 1 ± 0.2 m apmsl. This has a composite structure with an embryonic notch forming at modern sea level (Figure 6b). The embryonic notch was found at elevations of approximately the highest modern tidal range (~1 m) and have ‘overprinted’ the mid-Holocene sea cliff (Figure 6b). This may indicate that the proto-notch starts at the highest tidal range and is developing up/down with slow terrace uplift. The geomorphological characteristics of these notches, i.e., cut at modern high-tide into the vertical Holocene cliff of carbonate bedrock with a symmetric flattened U-shape, may be the result of quiescent conditions during the early stages of notch development. Such overlapping of the former and new erosional zones in Kamaran

Island (Figure 6b) corroborates the site's tectonic stability as the former erosional surface does not exceed the modern tidal range. It also suggests that the Kamaran Island has been stable for a considerable time (i.e., for at least the late Pleistocene). Another notch at ~ +4 ± 1 m apmsl (Figure 8b) is thought to be of LIg age, although corals sampled from this terrace were diagenetically altered and yield older ages than the LIg (Table 1).

A quantitative relationship between notch size, wave energy, and lithology has been suggested (e.g., Antonioli et al., 2015). These authors show that the vertical distance between the roof and the base of the notch is greater than the mean tidal range, but smaller than the maximum difference between tidal extremes (i.e., the maximum and minimum tides). However, this relationship may not be maintained for all notches, and it is not uncommon for notches to have height greater than the tidal range, and up to 3.2 times the tidal range in sheltered/exposed sites (Antonioli et al., 2015). Nonetheless, several studies have linked the width of wave-cut notches (i.e., the vertical distance between the base and the roof) to the amplitude of the mean tidal range (Trenhaile et al., 1998; Antonioli et al., 2015; Trenhaile, 2015; Rovere et al., 2016; Lorscheid et al., 2017). For example, where the height of the notch is greater than the modern tidal range and assuming the notch was formed by similar processes to today, the difference in the modern and palaeo notch amplitudes can be related to changes in tidal range (e.g., Antonioli et al., 2015; Lorscheid et al., 2017). Such comparisons provide a first-order estimate of possible changes in tidal amplitudes.

The notches in eastern Kamaran have U-shape morphologies (i.e., notch height exceeds the notch depth), which is greater than the modern tidal range of the area (~1 m). When coupled with the U-notch morphology with the staircase morphology from the same sites (Figure 7), this suggest co-seismic activity, as these terraces lie within the As-Salif Diapir zone. However, sea-level oscillations and/or a sequence of sea-level stillstands related to-differences in the tidal regime cannot be excluded. Alternatively, the U-shaped morphologies could suggest that the LIg notches (+3 to +4 m apmsl) were deeper originally, but weak host rocks and prolonged weathering led to shape modification and roof collapse. The presence of failed cliff material deposited at the toe of Kamaran Island sea cliffs (Figures 6 to 8) would support this interpretation. Deeper notches would require a prolonged contact and/or weak host rocks. Coseismic activity related to the As-Salif salt diapirism to the east of Kamaran Island could also have led to notch displacements and collapse.

5.3 Mid-Holocene sea-level highstand(s)

The global record of mid-Holocene sea level is complex and geographically divergent due to glacio-hydro-isostatic and water redistribution processes (e.g., ocean syphoning at the end of the dominant melting period ~6 to 7 ka) (Clark et al., 1978; Pirazzoli and Pluet, 1991; Mitrovica and Peltier 1991; Mitrovica and Milne, 2002; Lambeck et al., 2014). A sharp decrease in the rate of sea-level rise is predicted after ~6.8 ka, with low rates of change (> 1.42 mm/yr) for the remainder of the Holocene (Antonioli et al., 2015 and references therein). The combined deformation and gravitational response resulted in divergence in the timing and amplitude of the mid-Holocene highstand globally (Nakada and Lambeck, 1987; Pirazzoli and Pluet, 1991; Long, 2001; Mitrovica and Milne, 2002; Milne et al., 2009; Stattegger et al., 2013; Woodroffe and Webster, 2014; Lambeck et al., 2014). A spatially complex pattern is also predicted from the Red Sea, where the isostatic response is largely determined by water-loading (Red Sea, Indian Ocean and Mediterranean) (Lambeck et al., 2011).

Mid-Holocene highstands have been reported for several locations within the Red Sea. The complex spatial variability is expected due to the hydro-isostatic response in the basin to time-dependent water loading (Lambeck et al., 2011). GIA predictions for the Red Sea (e.g. Lambeck et al., 2011; Lambeck et al., 2012) produce high sea levels when ice melt was at its maximum rate, and the highstand is predicted to be more pronounced for both ends of the Red Sea regions compared to the central basin due to water loading from the Indian Ocean and the Mediterranean (Lambeck et al., 2011). In addition, as the glacio-isostatic signal is of the opposite sign to sea-level rise due to melt, mid-Holocene sea-level highstands are not expected for all locations in the Red Sea (Lambeck et al., 2011). Our well-constrained sea-level indicators, and a compilation of previously reported mid-Holocene highstand data (Friedman, 1968, Faure, 1975; Hötzl et al., 1984; Dabbagh et al., 1984; Al-Rifaiy and Cherif, 1988; Gvirtzman et al., 1992; Gvirtzman, 1994; Dullo and Montaggioni, 1998; Plaziat et al., 1995, 1998; El-Asmar, 1997; Carbonne et al., 1998; Moustafa et al., 2000; Shaked et al., 2004) (Figure 11), provide a valuable test of GIA models, Earth model parameter choices for this region, and sea-level predictions given that sea-level amplitudes are strongly Earth model dependent (~1 m at our study sites), with strongest dependence on the upper mantle viscosity (Lambeck et al., 2011). The data from the Yemeni Red Sea are especially useful as to date, observational data is scarce for the southern Red Sea.

U-series ages of coral samples from two locations on the As-Salif Peninsula (RH and OG) indicate that the terraces and associated geomorphological features are mid-Holocene in age, whereas the corals dated from the ~4 m terrace on Kamaran Island where highly altered and are assumed to be of Last Interglacial in age (Table 1). Our sites on the As-Salif Peninsula suggest some diapir influence, but that this diminishes away from the locus of the diapir, with successively less influence on the elevations of the Om Gedi and Ras Harafa terraces respectively. The two in growth position corals (+0.5 ± 0.2 m apmsl) from the Ras Harafa terrace have mid-Holocene ages (5,358 ± 33 years BP, inverse weighted mean), and are likely a maximum estimate of the age of the mid-Holocene highstand in this region of the southern Red Sea, given that they are below the maximum elevation of the notch cut into the same terrace. The notch itself likely represents the upper limit (elevation +1± 0.2 m apmsl, Figure 4) of the mid-Holocene sea-level highstand (i.e., mean sea level) at this site.

Our new data are broadly consistent with other mid-Holocene sea-level data for the Red Sea (Figure 11), and show the drop in relative sea level after the cessation of the main melt period at ~6 ka (Nakada and Lambeck, 1987; Mitrovica and Milne, 2002; Antonioli et al., 2015; Lambeck et al., 2014). In general, the more northerly sites have higher elevation mid-Holocene terraces, and older ages for the terraces than for the sites in Saudi Arabia at the centre of the basin (Figures 11 and 12) (Friedman, 1968; Gvirtzman, et al., 1992; Gvirtzman, et al., 1994; El-Asmer, 1997; Dullo and Montaggioni, 1998; Plaziat et al., 1998; Moustafa et al., 2000; Shaked et al., 2002; Faur, 1975; Hötzl et al., 1984; Hein et al., 2011), which is in broad agreement with GIA predictions for the mid-Holocene (Lambeck et al., 2011). Our new Yemen data also show older ages for the southern edges of the basin, and the elevation of the highstand is close to that predicted (~0.5 m) using the preferred Earth model (E3) of Lambeck et al. (2011). In detail, the elevation of our Yemen samples is very similar to the elevations given for the fossil terraces of Saudi Arabia (Dullo and Montaggioni, 1998), where a "lower" highstand is predicted, and also similar in elevation to portions of the Egyptian coast (24 to 26 °N; Plaziat et al., 1995, 1998), where a "higher" highstand are predicted from GIA modelling (cf. Lambeck et al., 2011). There may be tectonic, or neotectonic (e.g., due to salt diapirism) overprinting of the elevations and sea-level signal at other sites, but which have been explicitly accounted for in our study using local and regional mapping. This allowed us to disentangle the neotectonic overprinting and to determine the most likely elevation for the mid-Holocene highstand at the Ras Harafa site (i.e., the elevation of the notch at elevation +1± 0.2 m apmsl, Figure 4). Further data from the Red Sea, and the southern Red Sea in particular, is needed to more fully test the GIA models and associated sea-level predictions. A sufficiently dense geographical coverage is still lacking, and factors other than sea level (e.g., neotectonics) need to be disentangled by careful mapping at local/regional scales.

In summary, our observations from the southern Red Sea, compare favorably with the GIA prediction models of Lambeck et al. (2011), where the highest and earliest mid-Holocene sea levels occur between 6 to 5 ka in the southern (and northern) Red Sea basin and also with other observational data (Friedman, 1968, Faur, 1975; Hötzl et al., 1984; Gvirtzman et al., 1992; Gvirtzman, 1994; Dullo and Montaggioni, 1998; Moustafa et al., 2000; Shaked et al., 2002; Hein et al., 2011) from the basin (Figure 12). However, more high-quality data, with well constrained age and elevation uncertainties, is required to more fully test both the GIA predictions and Earth model parameter choices for the region.

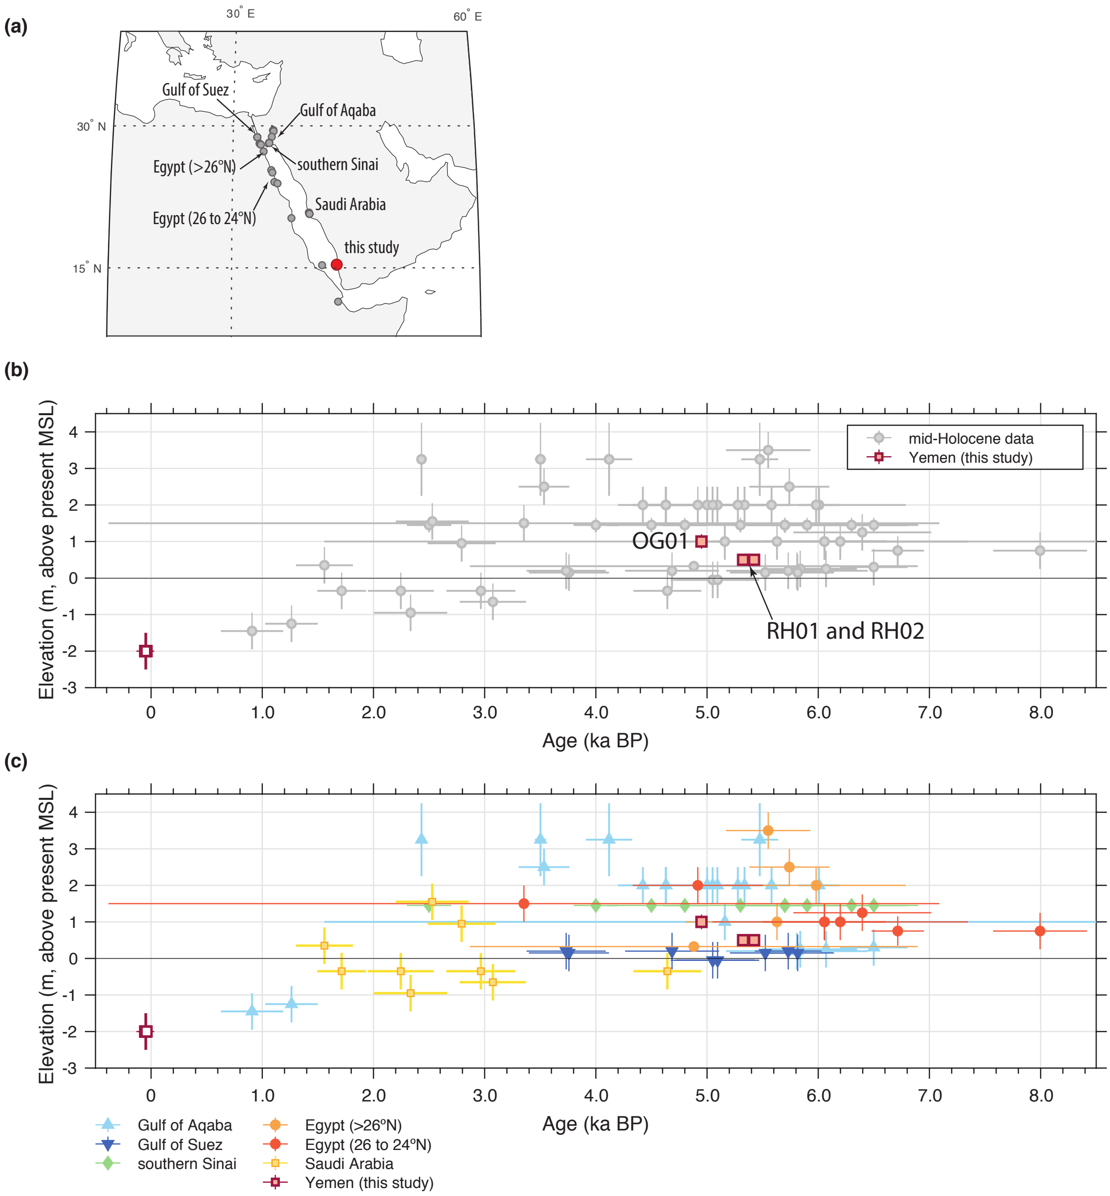

Figure 11: Elevation of the mid-Holocene highstand in the Red Sea. (a) map of mid-Holocene highstand sites (b) grey dots, reported mid-Holocene elevations and ages (Friedman, 1968, Faur, 1975, Hötzl et al., 1984; Gvirtzman, 1994; Gvirtzman et al., 1992; Dullo and Montaggioni, 1995, 1998; Al-Raifaiy and Cherif, 1988; Moustafa et12 al., 2000; Shaked et al., 2002; Hein et al., 2011) (radiocarbon ages have been recalibrated using the latest calibration curve (Marine20, Heaton et al., 2020) and a consistent ΔR (weighted mean ΔR = 176 ± 62 years (n = 9), Cember, 1989; Felis et al., 2004; Reimer and Reimer, 2020); filled red squares, dated fossil from As-Salif Peninsula and, open red squares, dated modern coral samples from Bab El-Mandab; (c) as in (b) but separated geographically by latitude. Uncertainties in age and

elevation are 2 sigma. (The compiled data is available here: doi: 10.6084/m9.figshare.13079240)

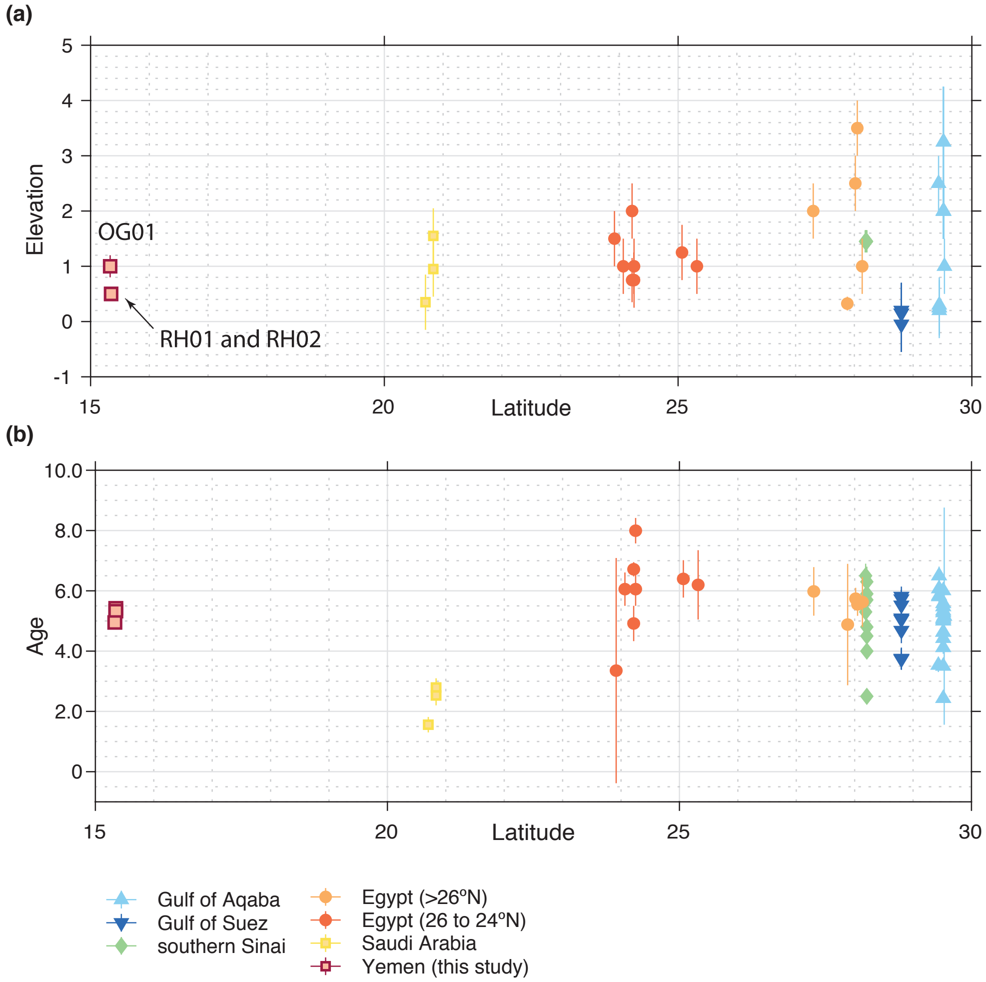

Figure 12: Elevation of the mid-Holocene highstand in the Red Sea. (a) grey dots, reported mid-Holocene elevations and ages (Friedman, 1968; Faur, 1975; Hötzl et al., 1984; Gvirtzman et al., 1992; Gvirtzman, 1994; Dullo and Montaggioni, 1995, 1998; El-Asmar, 1997; Moustafa et al., 2000; Shaked et al., 2002; Hein et al., 2011) (radiocarbon ages have been recalibrated using the latest calibration curve (Marine20, Heaton et al., 2020) and a consistent ΔR (weighted mean ΔR = 176 ± 62 years (n = 9), Cember, 1989; Felis et al., 2004; Reimer and Reimer, 2020); red squares, elevations of dated coral samples, this study; (b) as in (a) but separated geographically by latitude. Uncertainties in age and elevation are 2 sigma. (The compiled data is available here: doi: 10.6084/m9.figshare.13079240).

5.4 Tectonic Stability, neotectonics and salt diaprism in the Yemeni Red Sea

The development of the southern Red Sea islands and volcanic coastal formations has been primarily controlled by tectonics since the opening of the rift (Purser and Hötzl, 1988; Bosworth, 1994, 2015; Bosence, 2005; Rowlands and Purkis, 2015). Our study area (Kamaran and As-Salif Peninsula) is part of a salt diapir platform formed by a linear north-south trending salt diapir, which is bounded by a normal growth fault on the eastern margin and continues offshore for several kilometers (Bosence et al., 1998). The orientation of the island terraces in the southern Red Sea are closely related to fault lineaments, and the fault trends are also allied with swarm of high magnitudes earthquakes along the offshore of Kamaran and As-Salif regions.

The Yemeni Red Sea generally has lower seismicity and uplift compared to the northern part of the Red Sea and tectonic movements here are more localized and associated with salt diapirism. Seismic activity and tensional movements in the study region have stimulated the evaporites to rise and form a salt dome ~+18 m apmsl. The underlying evaporite unit makes the sites are more susceptible to localized crustal movements due to salt tectonics (Bosence et al., 1998). However, the influence of salt diapirism and/or tectonics appears limited and highly localized in the area, given the similarity in the elevation of the mid-Holocene notches on the As-Salif Peninsula (RH and OG), and Kamaran Island (+0.5 ± 0.2 m apmsl). However, we detect some limited neotectonism at the eastern Karaman Island site, where the terrace is uplifted up to ~ + 6 ±1 m (apmsl) relative to the main island, which has an elevation of ~ + 4 ±1 m (apmsl) (Figure 6a). The contrast in the faults flank elevations was a result of movement of the hanging-wall (seaward side) up relative to the stable footwall (landward side), suggests a thrust (reversed) fault. The fault can be easily traced as a discrepancy between the mid-Holocene wave cut cliff (at ~ +1.3 ± 0.2 m elevation) and the well-developed U-shape mid-Holocene wave-cut notch of ~ + 2.3 ± 0.2 m elevation. As the displaced layer is imprinted with an embryonic notch at the same height as the sea, the age of this fault is not older than the mid-Holocene, and is probably linked with the complex activity of the salt diaper.

Northern Kamran Island is sufficiently far from the influence of the salt diapir that the notches retain their asymmetrical V-shape. This is in contrast to the eastern portion of the island where coseismic activity associated with salt diapirism has likely contributed to modified the morphology of wave-cut cliffs and notches resulting in U-shaped notches. The change in the erosional base (which is limited by the tidal range) may also have been prompted by changes in sea level, wave energy and/or tidal regime leading to a widening, deepening and separation of notches and possible overprinting of older features (Schneiderwind et al., 2017).

6. CONCLUSIONS

We document palaeo sea-level indicators (fossil terraces, wave-cut notches and sea cliffs) for two locations (As-Salif and Karaman Island) in the Yemeni southern Red Sea and, using U-series dates of fossil corals in the same (underlying) unit, quantify the changes in sea level during the mid-Holocene and LIg. The spatial distribution, morphology and elevations of fossil terraces allowed us to disentangle the various processes, including the history of recent tectonic uplift. The relative consistency of the mid-Holocene geomorphic features suggests relative tectonic stability of the region with some minor diapir influence. These new observations improve our understanding of the local and regional history, providing constraints on the long-term rates of vertical movement that underpin models of Red Sea rifting. Additionally, given the relatively stable tectonic setting for the last ~6,000 years, the study locations, should be useful for reconstructing past sea-level changes.

We demonstrate the potential of tidal notches for reconstructing past changes in sea level in the region. Despite complications in the field (i.e., the obstruction of the vertex due to cliff failure), our new observations and detailed mapping of geomorphic features enabled us to account for neotectonics (e.g., salt diapirism, localised faulting). This allowed us to establish the elevation of the mid-Holocene highstand from wave-cut notches at ~1 ± 0.2 m (apmsl).

Our new southern Red Sea data thereby provide a valuable calibration dataset for geophysical models of the region, particularly as data for the southern Red Sea basin was previously lacking. Our new data, and compilation of the wider regional mid-

Holocene data suggest that the preferred Earth model parameters of Lambeck et al. (2011) provide sea-level predictions that are consistent with the available evidence. Our data go some way to addressing the 'incomplete record' of Holocene sea-level change in the Red Sea identified by Lambeck et al. (2011). However, more high-quality data is required.

The Yemeni Red Sea generally has lower seismicity and uplift compared to the northern part of the Red Sea, and tectonic movements here are more localized and associated with salt diapirism. However, some limited neotectonism in the eastern portion of the island has likely contributed to modify the morphology of wave-cut cliffs and notches resulting in U-shaped notches.

Acknowledgements

This project was funded by U.S Fulbright program and is a research scholarship given to the first author. The help extended by Prof. Mohammed Al-Wosabi and Dr. Aref Al-Sageer during the fieldwork is gratefully acknowledged. Many thanks go to Julie Retrum, Mellissa Cross, Yanbin for their help during U-isotope analysis at the University of Minnesota. Special thanks go to Rick Knurr for assistance in XRD analysis. Einas Al-Alimey, a Cultural Affairs Specialist at the U.S Embassy in Sana'a was of great help to this study. We are most grateful to Christopher Hein (Virginia Institute of Marine Science) for detailed reviews and comments that led to substantial improvements to this work.
