# Analysis of the load exerted by debris flows on filter barriers: comparison between numerical results and field measurements

Alessandro Leonardia, Marina Pirullia

<sup>a</sup>Politecnico di Torino Department of Structural, Geotechnical, and Building Engineering 24 Corso Duca degli Abruzzi, Turin, Italy

#### Abstract

The hazard posed by debris flows onto mountainous settlements often requires structural countermeasures, such as barriers, to be installed. There is a worldwide trend in employing barriers that are partially impervious to the flow, trapping the coarsest sediment, and reducing the erosive power of the flow early on. However, many design choices with respect to effectiveness and structural integrity are not trivial, because there is a poor knowledge of the flow-structure interaction mechanism. In this work, we report results from a monitoring campaign on a barrier installed within an experimental site. At the site, the structural response of the barrier is recorded any time an event occurs. However, the results exhibit features that do not fully reconcile with the load model prescribed by the available guidelines. To gather insight, we propose a numerical study based on the use of the Discrete Elements Method for the flow simulation and the Finite Element Method for the structural response of the barrier. The compatibility between site measurements and numerical output validates the use of the DEM-FEM model. It also highlights certain key details on the load pattern on the barrier that are not yet included in existing guidelines.

Keywords: Debris flow, filter barrier, site monitoring, numerical modelling, discrete element method

#### 1. Introduction

Steep creeks in mountainous terrains are subject to hazards such as debris flows (Hungr et al., 2001; Petley, 2012). These count among the most dangerous natural events, posing a constant threat to settlements on mountainous terrain and considerably handicapping the design and maintenance of infrastructures (Hungr and Jakob, 2005). Debris flows are typically rich in coarse sediment, and can induce significant bed erosion and entrainment. This inflates the amount of flowing material, in turn leading to growing erosive power (Pirulli and Pastor, 2012).

To check the hazard related to this feedback mechanism, dams and barriers are often installed in the catchment. The recent years have seen a growing use of barriers with a certain degree of permeability (filter barriers), thus retaining only a fraction of the flowing mass. These barriers are often designed to retain the coarsest debris by inducing partial or total jamming at the outlets (Piton and Recking, 2016). At the same time, they allow fine sediments, which have reduced erosion potential and can be more easily conveyed and dosed, to filter downstream. These designs are a compromise between the need to trap sediments and break the energy of the flow, and the requirement to keep maintenance work as low as possible. This determines a lower maintenance cost and environmental impact with respect to impervious barriers. Example of structures of this type are provided in Fig. 1: one or multiple outlets are present. In these cases, the interaction mechanism between flow and structure is not trivial: the barrier, while breaking the energy of the flow,

also induces an alteration of pore pressure, and an activation of inter-particle friction (Song et al., 2018; Cabrera and Estrada, 2019).

The impact of a mass characterized by a significant content of grains on an impervious barrier has been extensively studied (e.g. Albaba et al., 2015; Gabrieli and Ceccato, 2016; Calvetti et al., 2019). However, it is not clear whether the results of these studies can also be extensively applied to filter barriers. From recent studies (e.g. Leonardi et al., 2019), it emerges that the presence of an outlet can induce accumulation of stresses, which can further complicate the estimation of the maximum expected load. This makes a rational design, both for performance and structural integrity, problematic. Additionally, few design prescriptions and guidelines are available worldwide. Here we refer to the Austrian guideline series ONR 2480X (Rudolf-Miklau and Suda, 2011), and to the set of guidelines developed in Hong Kong (Kwan, 2012). The former recommends to estimate the impact pressure with a formula based on a combination of momentum exchange and gravitational load (Suda et al., 2012). The latter recommends a pressure proportional to the square of the front velocity. In both approaches, the dynamic load is considered uniform across the barrier surface.

These guidelines do not directly consider jamming, i.e. that the outlets can clog through the formation of granular arches (Janda et al., 2008; Chevoir et al., 2007). The load distribution on the barrier is assumed to act only in the direction of the incoming flow (Hübl et al., 2009; Kwan, 2012). The consequences of this simplification have not yet been completely explored. From small-scale experiments, it is clear that mo-

mentum transfer in the direct (10) parallel to the mean flow is the main source of load (e.g. Canelli et al., 2012; Koo et al., 2017). However, granular material close to the jamming transition can exert forces with intensity and directions that are not easily predictable (Bharadwaj et al., 2006; Hidalgo et al., 2013). If not correctly accounted for, this could potentially lead to premature failure of a barrier, or to damage that reduces its operational raction occurring between filter

experimental site and the collected datasets. We proceed by outlining the DEM-FEM framework adopted for the back analysis. Subsequently, we show how the numerical procedure reconstructs a load pattern that is compatible with the recordings obtained on site. Using this approach, we compute a more realistic multi-surge sequence of impacts on the barrier, which describes a typical event in the monitored basin. We describe the obtained load pattern, and determine in which regards the DEM-FEM model provides a more conservative estimation of the impact load compared to reference design guidelines. Based on these results, we provide a set of suggestions that aim at improving the design of this type of barriers, and of effective monitoring systems.

# 2. The Grand Valey experimental site

# 2.1. Site description

The site used as study-case in this work is located in the municipality of St. Vincent, within the Aosta Valley Autonomous Region, Italy (see Fig. 3). The settlement is partially located on the deposition fan of the Grand Valey creek, which drains an area of 5.22 km², at an altitude between 700 m and 2719 m a.s.l., the highest point being Mount Zerbion.

The mean slope of the creek bed is 38%, which decreases to 12% on the alluvial fan. Close to the hamlet of Perrière, at an altitude of about 1150 m a.s.l., the creek branches into two channels, labeled A and B in Fig. 3. Both branches drain a part of the basin that is characterized by steep slopes at high altitude, composed of heavily fractured schists with subordinate phyllitic levels, serpentinite, and prasinites metagabbros. These slopes are only partially covered by vegetation and are prone to be easily eroded by heavy or moderate rains, such as those routinely recorded during spring and summer. The combination of these factors makes both branches prone to the release of debris flows with annual frequency. Similar conditions can be encountered in certain sites in the Italian Dolomites (Tecca and Genevois, 2009) and in the Pyrenees (Pastorello et al., 2018).

A list of all documented events from 2004 to the present day is provided in Table 1. A debris flow in 2004 reached the settlement of St. Vincent, causing limited damage but, at the same time, highlighting hazard exposure. The sequence of events in 2008 heavily damaged the barriers installed in the main channel, with debris reaching the alluvial fan in proximity to the settlement. This prompted a general revision of the hazard management techniques by the local government (Pirulli et al., 2014a). To reduce the risk associated with future events, a sequence of structural countermeasures was therefore installed, and available structures were upgraded. The goal was to reduce the amount of debris that reaches the lowest part of the basin, and in particular to retain the coarsest sediments as upstream as possible. The site now features two filter barriers (at location 1 in Fig. 3), three steel-ring nets (at location 2), and a slit dam (location 3).

# 2.2. Countermeasures

The two filter barriers are located immediately after the confluence of the two branches, on a section with a gentle slope

(around 12°). This is directly below the steep slopes responsible for the mobilization of coarse material (A2 and B1 in Fig. 3). The barriers are essentially rack structures, built by inserting a sequence of slender steel bars on a concrete basement. They are routinely hit by flows with relatively small volume (usually a few thousand cubic meters), surging through multiple consecutive impulses and with a high content of coarse grains. One of the filter barriers, the first impacted by flows, is shown in Fig. 2(a).

Each barrier (Fig. 4) features a sequence of eighteen steel I-beams (IPE 270), with spacing i = 0.6 m, mounted on a concrete basement. Between two consecutive beams, an outlet with transverse size S = 0.47 m is present. The two structures, including the lateral wings, span the whole width of the channel (17 m), and are separated by a retention basin 46.5 m long. Together, they can retain about 5000 m<sup>3</sup> of debris. They are designed to filter out the coarse grains, inducing deposition in the retention basin, while allowing fines and water to flow downstream. This system requires regular maintenance: the basin

to fully represent the real grain-size distribution at the site scale. Thus, a rigorous treatment of debris material in this context remains beyond the reach of current state-of-the-art methods.

We therefore adopt a strategy based solely on the application of DEM for the flow simulation. This method treats the debris mass as an assembly of spherical particles. This has two important consequences. Firstly, with DEM there is a strong limitation on the number of grains that can be modeled. Secondly, the use of spherical particles implies that interlocking effects due to non-spherical shapes cannot be explicitly described. From Iverson (2015), we know that an assembly of spheres is less compressible compared to an assembly of angular particles. Furthermore, the clogging probability can be severely altered by particle anisotropy (Ashour et al., 2017). The addition of rolling resistance to the contact model (as described below) partially addresses this issue (Marchelli et al., 2019). In spite of these necessary simplifications, DEM remains to date the most comprehensive and commonly used tool capable of reproducing the interaction between a mass composed of large grains and solid obstacles (Bharadwaj et al., 2006; Albaba et al., 2015), especially when a jamming transition occurs (Albert et al., 2000; Leonardi et al., 2019).

It should be noted that numerical methods based on a continuum approach, such as the Lagrangian finite elements (Kwan et al., 2015), the material point method (Llano-Serna et al., 2016), fictitious-domain fluid solvers (Cheng et al., 2018), the lattice-Boltzmann method (Leonardi et al., 2015; Ding and Xu, 2018), or smoothed particle hydrodynamic (Dai et al., 2017; Huang et al., 2012) are also suitable for reconstructing the fluid-structure interaction. However, they rely on an equivalent-fluid description of the material, effectively smoothing the effect of discrete loads induced by particles (Ceccato et al., 2018). Furthermore, these methods cannot simulate granular jamming. They are therefore inappropriate for the simulation of granular clogging.

The DEM solver used here is based on the code by Leonardi et al. (2016), with the modified contact model described by Marchelli et al. (2019). The reader is redirected to those works for the full theoretical background, the code layout, and a definition of the simulation parameters listed in the following sec-

tions.

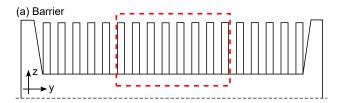

The contact model is schematically represented in Fig. 8. The particle elastic properties are defined with a Young's modulus E and a Poisson coefficient  $\nu$ . The contact model employs a non-linear damped Hertzian law for the normal component of the collision force (Pöschel and Schwager, 2005). The dissipation is adjusted in order to obtain a constant coefficient of restitution, as in Tsuji et al. (1992). In the tangential direction, contacts are frictional with a coefficient of static friction  $\mu_{\rm s}$ . The frictional behavior is implemented using elastic springs as in Luding (2008). The tangential spring stiffness, in analogy to the contact model in the normal direction, is determined by Eand  $\nu$ . Relative rotation of colliding particles is subject to an additional dissipation source. Following Marchelli et al. (2019), this is implemented with a rolling resistance mechanism, whose intensity is governed by a dimensionless rolling coefficient  $\mu_r$ . With this model, grains can spontaneously jam, clogging outlets multiple times larger than their size, as is observed on the field (Piton and Recking, 2016).

Typical values for dense gravel are assigned to the particle Young's modulus E, the Poisson coefficient  $\nu$ , and the coefficient of restitution c. To determine the values of  $\mu_s$  and  $\mu_r$ , the procedure presented by Marchelli et al. (2019) is used. In the procedure, each couple of  $\mu_s$  and  $\mu_r$  is linked to a single value of the angle of repose, obtained through heap-formation simulations. Specifically, the values used in this work correspond to an angle of repose of about 30°, again a typical value for gravel. Note that the parameters can also alternatively be determined from triaxial tests, as in Cheng et al. (2017).

The DEM simulation environment is illustrated in Fig. 9(b). The simulation geometry is a simplified version of the site in St. Vincent. A rectangular channel is built using flat, frictional walls with constant friction angle  $\phi=30^\circ$  at the bottom and at the sides. The channel is inclined at a constant angle of  $12^\circ$ . To keep runtime reasonable, the channel width is reduced to 4.2 m, corresponding to eight metal bars. Only the central part of barrier and flow is therefore simulated. The channel length is also reduced to 10.0 m.

The granular mass representing the flow front is set up by generating a debris sample within a partition of dimensions  $5.0 \text{ m} \times 4.2 \text{ m}$ , respectively in the x and y directions (see the inset in Fig. 9(b)). All particles are released at the simulation start with a uniform velocity  $v_f$ . The mean grain radius can be either D = 0.16 m, 0.20 m, or 0.25 m. These are typical sizes for the grains that clog the barrier at the St. Vincent site. The three samples feature grains that exhibit different size ratio with respect to the outlet size:  $S/D \simeq 3.0$ , 2.5, and 2.0, respectively. These also correspond to different behaviors when the grains flow through the outlets. The largest grains  $(S/D \simeq 2.0)$  clog the outlets quickly, while the smallest  $(S/D \simeq 3.0)$  have a lower probability to jam. Using the small grains, much more material flows downstream before the system stabilizes (Marchelli et al., 2019). In all samples, a 10% dispersity in the radius is included to avoid excessive granular crystallization (Bi et al., 2005).

The barrier is placed at a distance of 0.5 m from the partition that contains the grains, see Fig. 9(b). It mimics the one in St. Vincent, with certain geometrical simplifications. The

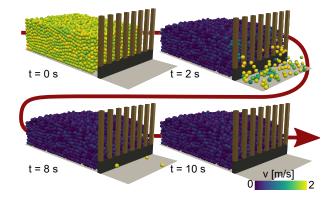

Figure 10: Representation of the impact mechanisms that reconstructs the debris flow front that impacted the barrier on the 9<sup>th</sup> of June.

The material parameters for all FEM simulations are constant and listed in Table 3. Their definition is standard in terms of FEM modeling, and all simulations are performed in the linear elastic regime. The stress-strain pattern, and its evolution over time, is obtained by running linear explicit dynamic analyses with a central-difference scheme (as in Liao and Liu, 2017). The Rayleigh damping factors however cannot be easily determined directly (Baillargeon et al., 2004). They should also take into account the damping contribution of the surrounding fluid, which is significant since the bars are almost encircled by debris. This is one of the strongest limitations of this work. The coupling algorithm transfers information in one direction only. Impact forces are transmitted from DEM to FEM, but information on the barrier deformation is not transferred back from FEM to DEM. In order to bypass this issue, the structure is overdamped (see Table 3). In any case, under impact load the maximum and minimum stresses are scarcely affected by a change in these values (Chopra, 2017), as confirmed by our tests and by similar studies in the literature (Kiakojouri and Sheidaii, 2018). As an output of each dynamic analysis, we obtain a time-history of strain distributions along the barrier. This includes strains in the location on the bars that is equivalent to where the extensometers are mounted in the field. Therefore, the two datasets are comparable.

The described numerical setup is used in the following sections with a twofold goal. Firstly, we validate the approach by back-calculating the measurements obtained during the June 9th event in St. Vincent (Fig. 7). Secondly, the approach is used to test the performance of the barrier over a sequence of surges, as prescribed by the Austrian guidelines ONR 24801, and those used in Hong Kong (Kwan, 2012).

#### 5. Back-calculation of field measurements

When the debris flow that generated the set of recordings shown in Fig. 7 happened, a team of technicians was operating in the area. From an analysis of the amateur video recorded in that instance, we know with rough precision the kinematics of the flow that impacted on the barrier. The front velocity was close to  $v_f = 2 \text{ m/s}$ , and the flow front had a thickness that

peaked at 3/4 of the beam height. Before the event, the basin was only marginally filled with debris.

Using the procedure described in the previous section, we perform a back-calculation of the event. The numerical parameters used in the DEM simulations are listed in Table 4. To follow up from the field observations, we release three granular samples onto the barrier at a uniform velocity of  $v_f = 2.0 \text{ m/s}$ , and with maximum thickness 1.6 m. The samples feature particles with different diameters, and different interaction mechanisms when hitting the barrier. The results from the smallest diameter are illustrated in Fig. 10. After an initial momentous impact, the debris flows through the outlets for a time span that depends on the ratio between the outlet size and the mean grain diameter, S/D. For the smallest particles, a stable static configuration is reached after 10 s. Conversely, the large grains clog almost immediately (< 1 s).

For an analytical estimation of the overall load, the dynamic formula (as in Eq. 1) is used here, assuming a unitary empirical coefficient (k = 1). In this approach, the expected impact force  $F^*$  and bending moment  $M^*$  on a bar can be computed using the velocity-dependent impact pressure  $q_d$  multiplied by the area of influence of a single bar:

$$F^* = \rho_b v_f^2 i H_B \tag{4}$$

$$F^* = \rho_b v_f^2 i H_B$$
 (4)  

$$M^* = 0.5 \rho_b v_f^2 i H_B^2$$
 (5)

where  $v_f$  is the front speed used in the simulation,  $H_B$  is the bar height, and i the bar spacing (see Fig 4). The bulk density of the debris,  $\rho_b$ , is computed as  $\rho_b = \rho \phi$ , where  $\rho$  is the grain mass density from Table 4, and  $\phi$  is the solid volume fraction, assumed to be constant and equal to  $\phi = 0.6$ , a typical value for monodisperse grains in a dense packing (Choi et al., 2016).

In the simulations, the forces exchanged between flow and barrier are recorded along the bars. The outcome of this process is shown in Fig. 11. In the figure, each plot illustrates a different simulation, i.e. a different dimensionless outlet size S/D. Within each plot, the points represent impulsive forces exerted on the barrier by the flow, divided by the reference force  $F^*$ computed with Eq. 4. The forces are illustrated using circular coordinates, where the radial direction represents the magnitude

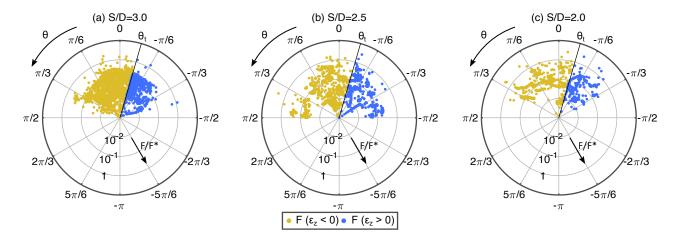

Figure 11: Scaled impact forces,  $F/F^*$ , recorded at different levels on the bars. One point every 10 samples is shown, for clarity. Each plot illustrates the results obtained with a different granular assembly, therefore with a different mean grain diameter.

of the impact:

$$F = \sqrt{F_x^2 + F_y^2} \tag{6}$$

and the circular coordinate  $\theta$  is the angle of incidence, as illustrated in Fig. 6 and defined by:

$$\theta = \operatorname{atan}\left(\frac{F_y}{F_x}\right) \tag{7}$$

If a quasi-static approach is used, each impact generates a shear F and a bending moment  $M = F \times H$  at the section where the experimental sensor is located, where H is the height difference between the location of the impact and the location of the sensor, as illustrated in Fig 6. Rewriting Eq. 3, it is evident that a moment M can generate either positive or negative strains, depending on the angle of incidence  $\theta$ :

$$\varepsilon_z = -\frac{M}{E} \left( \frac{s_y \sin \theta}{I_{yy}} + \frac{s_x \cos \theta}{I_{xx}} \right) \tag{8}$$

In this simplistic view, there is a threshold angle  $\theta_t$  that determines whether the impact generates positive or negative strains. This is a simple function of the bar section and of the location of the sensor, as provided below:

$$\theta_t = \operatorname{atan}\left(-\frac{I_{xx}S_y}{I_{yy}S_x}\right) \tag{9}$$

The initial particle velocity is aligned with the channel and therefore orthogonal to the barrier. Nevertheless, the impacts reported in Fig. 11 have a wide range of angles of incidence. The majority of high-magnitude impacts are located at around  $\theta = 0$ . However, a significant portion of strong events are reported over the whole range  $-\pi/3 < \theta < \pi/3$ .

About 30% of the impacts have an angle of incidence  $\theta > \theta_t$ . These bend the bars in a direction that results in traction of the sensors ( $\varepsilon_z > 0$ ). These are shown in Fig. 11 with dark color (blue), while those generating compression ( $\varepsilon_z < 0$ ) are reported in a light color (yellow). Conversely the simple orthogonal load model shown in Fig. 5(a), would determine an

angle of incidence always equal to  $\theta = 0$ , thus oversimplifying what is observed in reality.

In order to compare the field measurements with the simulations, the set of load time-histories on the bars are plugged into the FEM model onto the beams, using the procedure described in the previous section. Through the dynamic analyses, the external loads are thus converted into full time histories of strain/stress fields. In particular, the time-histories of resultant moments  $M_{\rm n}$  on each beam at the section where the sensor is located can be computed.

From the results of the simulations, it is clear that the angle of incidence significantly influences the strain measured by the sensor. Unfortunately, this implies that every value of  $\varepsilon_z$  recorded in the field can be obtained with multiple combinations  $(M_s, \theta_s)$ . The measurements, therefore, cannot be exclusively associated to unique values of bending moment.

No quantitative comparison can therefore be carried out between field data and simulations. However, we may check whether the simulations yield results that are compatible with the field data. This procedure is illustrated in Fig. 12, using the same plot style adopted for Fig. 11. We first extract the maximum and minimum strains recorded by every bar during the June 9<sup>th</sup> event:  $\varepsilon_{z,max}$  and  $\varepsilon_{z,min}$ , respectively. Typically,  $\varepsilon_{z,max}$ is positive, and  $\varepsilon_{z,min}$  is negative. Each of these values can be induced by multiple couplets  $(M_s, \theta_s)$ . These are plotted as loci of points (lines) in Fig. 12, and compared with the moments obtained with the DEM-FEM simulation procedure. In particular, they are compared with those moments that induce the maximum and minimum strain in the bars at the sensor location. Before extracting the maximum and minimum numerical moment, the simulation data is re-sampled at 0.87 Hz, which is the sampling frequency of the strain gauges on site. In this way, experimental and numerical datasets become comparable.

Fig. 12 shows that the simulation results are fully compatible with the field recordings. In other words, the type of load obtained in the simulations results in a strain pattern on the barrier that exhibits the same features observed in the field. In particular, both tension and compression values are recorded. Around the area of the graph that corresponds to the prediction

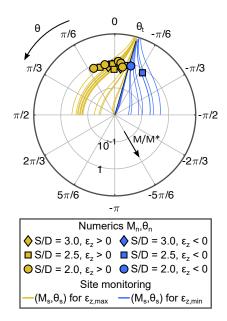

Figure 12: The maximum bending moments computed with the FEM-DEM simulations on the section corresponding to the locations of the field sensors  $M_{\rm n}$ , and corresponding angles of incidence  $\theta_{\rm n}$ . This is compared to lines representing the combinations of bending moment  $M_{\rm s}$  and angle of incidence  $\theta_{\rm s}$  that correspond to the maximum and minimum strains  $\epsilon_{\rm z}$  recorded by the extensometers.

given by the dynamic formula,  $M/M^* = 1$ , the numerical angles of incidence correspond to those from the site recordings, i.e. in the range  $-\pi/12 < \theta < \pi/12$  for large values of S/D and  $-\pi/6 < \theta < \pi/6$  for small values.

# 6. Performance under multi-surge load

From the results of the previous section, it emerges that an orthogonal load model is not always appropriate for the design of such structures. We thereby explore the consequences of the alternative load model provided by the DEM simulations.

Following the load setups suggested by the Austrian and Hong Kong guidelines, a multi-surge process is simulated.

Table 5: Geometry and characteristic parameters used for the multi-stage DEM simulations

DEM parameters (flow)						
Particle type	Small	Medium	Large			
Particle diameter $D$ [m]	0.167	0.200	0.250			
Outlet size $S/D$ [-]	3	2.5	2			
Particle number (stage 1)	11200	5888	3211			
Particle number (stage 2)	12272	6414	3211			
Particle number (stage 3)	22437	12008	6630			
Particle density $\rho$ [kg/m <sup>3</sup> ]		2630				
Young's modulus E [Pa]		$1.2 \cdot 10^9$				
Poisson ratio $\nu$ [-]		0.3				
Restitution coefficient $c$ [-]		0.8				
Friction coefficient $\mu_s$ [-]		$tan(30^{\circ})$				
Rolling coefficient $\mu_r$ [-]		0.07				
Tangential damping $\alpha_t$ [-]		0.5				

Three simulations are performed for each particle type. The initial setup for each simulation is illustrated in Fig. 13, and the DEM simulation parameters are gathered in Table 5. Stage 1 corresponds to a single surge of thickness comparable to the barrier height. Stage 2 represents a later surge impacting a barrier which has been partially filled by the deposit left by a previous surge. Stage 3 describes a surge that approaches a filled barrier. In the latter case, the total flow level surpasses the barrier height, causing significant overflow, as in Faug et al. (2011). For each stage, the initial velocity of the surge particles is fixed at  $v_f = 2.0$  m/s, as in the simulations presented in the previous section. The remaining particles, constituting the deposit resulting from the precedent stages, are free to move but have zero initial velocity.

This setup therefore reconstructs a typical multi-surge event. It does not, however, describe the limit situation under which the barrier in St. Vincent is supposed be functional, which corresponds to similar flow thicknesses (and surge sequences), but higher velocities (up to  $v_{\rm f}=5.0~{\rm m/s}$ ). Therefore, it is expected that the barrier remains within the elastic limit, and that the surges described by the three stages do not induce irreversible deformations to the structure.

The load exerted during the three DEM stages is concatenated, and plugged into the FEM model. The FEM simulations thus yield the time-history of stresses on the barrier during the whole multi-surge process. The FEM parameters (collected in Table 3) do not differ from those used in the previous sections.

The maximum bending moments at the base of each bar are shown in Fig. 14 for each stage, and each dimensionless outlet size S/D. Stage 3 induces the highest load, even though the surge flows over an almost entirely filled barrier, directly hitting the bars only at the very top. This is consistent with the observations concerning the premature failure of the dam in St. Vincent in 2014. The surge that caused the collapse flowed over a barrier that had already been partially clogged with material from a precedent event.

To compare the performance of the barrier with respect to structural integrity, we compute the moment of first plastic deformation  $M_{\text{vield}}$  as a function of the angle of incidence  $\theta$ :

$$M_{\text{yield}} = -\sigma_{\text{yield}} / \left( \frac{h_y \sin \theta}{I_{yy}} + \frac{h_x \cos \theta}{I_{xx}} \right)$$
 (10)

where  $h_x$  and  $h_y$  are the IPE 270 section dimensions (see Table 2). The admissible bending moment is much smaller if the bar is transversely loaded, due to the large difference in the inertia moment in that direction  $(I_{yy})$  with respect to inertia around the strong axis  $(I_{xx})$ .

From the DEM-FEM simulations, we extract, for each bar, the combinations of M and  $\theta$  that lead to the largest absolute values of  $\varepsilon_z$  on the bar. These values are compared to the maximum admissible moment  $M_{\rm yield}$ , of the IPE 270 section, as computed using Eq. 10 (see Fig. 14). Within simulations with similar geometrical configurations (i.e. same stage) the results vary with respect to the S/D ratio. Larger particles induce a slightly higher load than smaller ones, as expected. Moreover, they induce loads with a much larger angle of incidence  $\theta$ . This is due to the higher probability of jamming, which increases sharply

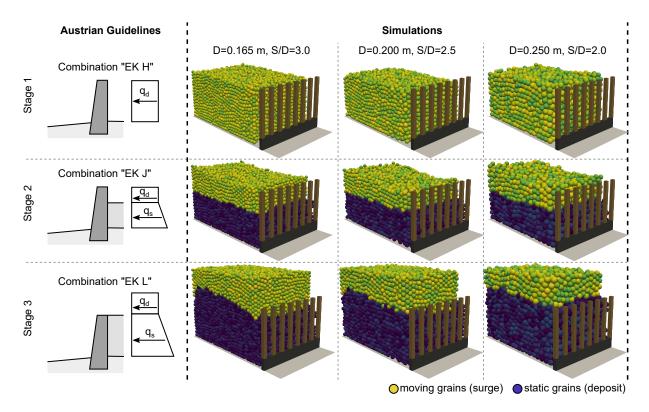

Figure 13: Graphical illustration of the initial setup used for the multi-stage simulations. The three surge configurations are inspired by the Austrian guidelines ONR 24801, an extract of which is reported in the left column. In the guideline load combinations, static grains deposited after precedent events exert a static load  $q_s$  on the barrier, while surging grains exert a dynamic load  $q_d$ .

with S/D (Marchelli et al., 2019). If jamming occurs rapidly, dynamic impact forces are transferred though granular arches early on, with significant self-balanced transverse loads.

From Fig. 14, it appears that the simulations with the largest particles induce a load that causes irreversible deformation of the bars. This, in spite of the front impact speed  $v_f = 2$  m/s being significantly lower than the one the barrier was originally designed to withstand ( $v_f = 5$  m/s). The outlet clogging induces additional transverse loads on the structural elements, which can contribute to premature failure of the barrier if not taken into account in the design process. This can be easily prevented by employing a section with similar dimension, but with symmetrical stiffness in the two main directions. For example, the use of a square hollow section with a 250 mm width and a 6 mm thickness (HSS 250) would have resulted in the barrier responding to all stages within its elastic limit, see Fig. 14.

#### 7. Conclusions

Barriers that filter the coarsest grains are an effective measure to reduce the hazard associated with debris flows. In this study, we presented results from one barrier of this type, installed in the Italian Alps, and fully equipped with a monitoring system that tracks the deformation of pivotal structural elements. However, the strains recorded on-site are not compatible with the load model that is usually used to design this type of barrier.

The recordings obtained during an event in June 2016 are thus compared to the results obtained with a numerical model.

The model couples DEM and FEM, and is therefore able to simulate with a good degree of precision both the surge impact process and the corresponding strain/stress field of the barrier. The results of the simulations are compatible with the field measurements, therefore validating the approach. They further provide valuable additional information on the space distribution of impact forces.

The results highlight how the load pattern on a filter barrier can be different from the one that is suggested by existing guidelines. When the material flows through the outlets, significant momentum is transferred to structural elements, transversely to the main flow direction. From the results of our analyses, we suggest testing the barrier design for additional transverse loads. The barrier should withstand loads characterized by angles of incidence within the  $-\pi/3 < \theta < \pi/3$ range. This is particularly relevant if the grains are large with respect to the outlet size. Furthermore, significant transverse components are also recorded when an overflow scenario is simulated, i.e. a case when the surge directly impacts the barrier only marginally. As a general consequence, structural elements should not have a significant difference in stiffness in the streamwise and transverse direction: they should perform well under biaxial bending. This is particularly important for structures that may clog quickly, such as filter barriers with small openings.

For the barrier installed at the experimental site in St. Vincent, and subject to the monitoring campaign, this has been shown to have important implications on the design safety. In

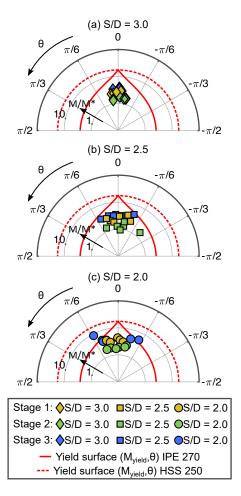

Figure 14: The bending moments giving the most critical conditions on the bars, as reconstructed with the multi-stage DEM-FEM procedure. The yield moment of the bars, as a function of the angle of incidence, is also displayed.

fact, the barrier analyzed hereby was not capable of withstanding the load obtained from the DEM-FEM analysis without incurring in irreversible damage. This alone cannot explain the 2014 collapse, in which even the concrete basement was heavily damaged. However, irreversible damage to the bars can change the bar spacing, therefore altering the filter properties of the barrier. This implies a loss of functionality, which should be avoided.

Finally, the simulations highlight a weak point in the monitoring station used in St. Vincent. In order to effectively monitor the structural response of the barrier, at least two strain gauges per element are necessary. An additional gauge positioned on the opposite flange would record a second value of  $\varepsilon_z$ , from which both the intensity of the bending moment and the angle of incidence could be unequivocally determined. Such a system would allow a reconstruction of the exact load distribution on the filter elements without a priori assumption.

#### Acknowledgements

The monitoring system in St. Vincent was funded by the RISKNAT project - Operational programme Italy - France (Alps - ALCOTRA) 2007-2013, the Mhymesis - Modelling Hazard of hYperconcentrated Mountain flows: a wEbgis SImulation System project 2015-2017 and C. Scavia's research funding (Politecnico di Torino). The Authors wish to thank V. Segor, L. Pitet and P. Gaia (Aosta Valley Autonomous Region) as well as M. Barbero, F. Barpi, M. Borri-Brunetto, and O. Pallara (Politecnico di Torino) for the design and configuration of the monitoring system. The authors are grateful to E. Calcagno for his help in generating and processing the FEM model, and to M. Ceccarelli and A. Lombrino for the interpretation of part of the monitoring data. Computational resources were provided by HPC@POLITO, a project of Academic Computing within the Department of Control and Computer Engineering at Politecnico di Torino (www.hpc.polito.it).
