Keywords: Blind source separation Independent component analysis Tensor

ABSTRACT

Independent Component Analysis (ICA) is a fundamental method for Blind Source Separation (BSS). Classical ICA takes data matrix input formed by vector data. This paper focuses on ICA for BSS with third-order data tensor input formed by matrix data, such as 2D images. Two approaches exist for this problem. The first approach reshapes each matrix into a vector to apply classical ICA, with structural information lost. The second approach unfolds a data tensor into a data matrix along different modes to perform classical ICA mode-wise, which partially preserves structures but has strong or ill BSS assumptions. This paper proposes a third approach via RAndom Matrix ICA (RAMICA) modeling. RAMICA works on data tensor directly, without vectorization or unfolding, and preserves row or column structures under more general BSS assumptions. We develop the RAMICA model, algorithm, and related theories via defining new statistics for random matrices and new procedures for whitening and independent component estimation. We study the identifiability, higher-order extension, and relationships with existing methods. Experiments on both synthetic and real data show superior BSS performance of RAMICA over competing methods and offer insights on the trade-offs between different factors.

1. Introduction

Blind Source Separation (BSS) [1] assumes that observed data are generated from unknown *latent sources*, and aims to recover these sources from the observations only. Independent Component Analysis (ICA) [2,3] is a fundamental method for BSS. Classical ICA methods treat *P* sources as random variables, and assume they are mutually independent and linearly mixed to produce *M* observations $\{x_m\}$ as:

$$x_m = a_{m1}s_1 + \dots + a_{mP}s_P, \tag{1}$$

where random variables are <u>underlined</u>, x_m is the *m*th observation, $\underline{s_1}, \ldots, \underline{s_P}$ are the latent sources named as *Independent Components* (ICs), and a_{m1}, \ldots, a_{mP} are mixing coefficients. Stacking random variables into vectors, the *vector-matrix notation* of (1) is:

$$\underline{\mathbf{x}} = \mathbf{A}\underline{\mathbf{s}} \in \mathbb{R}^M,\tag{2}$$

where $\underline{\mathbf{x}} = [\underline{x_1}, \dots, \underline{x_M}]^{\top}$ and $\underline{\mathbf{s}} = [\underline{s_1}, \dots, \underline{s_P}]^{\top}$ are observation (mixture) and source random vectors, and $\mathbf{A} = \{a_{mp}\} \in \mathbb{R}^{M \times P}$ is the un-

known deterministic matrix, namely *mixing matrix*. It is usually assumed that M = P so that $\mathbf{A} \in \mathbb{R}^{P \times P}$ is square, which we follow hereafter. Considering *T* available samples of observations \mathbf{x} (sources \mathbf{s}), align all samples in column to form the *data matrix* \mathbf{X} (*source matrix* \mathbf{S}). We can then write the ICA model in \mathbf{X} and \mathbf{S} as:

$$\mathbf{X} = \mathbf{AS} \in \mathbb{R}^{P \times T}.$$
(3)

In other words, **X** contains *T* samples $\mathbf{x}(1), \ldots, \mathbf{x}(T)$ of *random vector* \mathbf{x} in column, and **S** contains *T* samples¹ of random vector \mathbf{s} in column. ICA aims to estimate the source matrix **S** and the mixing matrix **A** simultaneously with data matrix **X** as the only input [4].

Real-world data are often matrices or even higher-order tensors, such as multichannel ElectroEncephaloGraphy (EEG) signals, images, videos, or social networks [8]. In such cases, all observed data of a particular problem form a *data tensor* \mathcal{X} with their natural multidimensional structures. All observed matrix data form a third-order data tensor, while all observed Nth-order tensor form an (N + 1)th-order data tensor. We can view such data tensor as

¹ In this paper, the term 'sample' refers to samples of random variables, and the number of observations (*P*) is the number of data samples/examples in typical machine learning terminology.

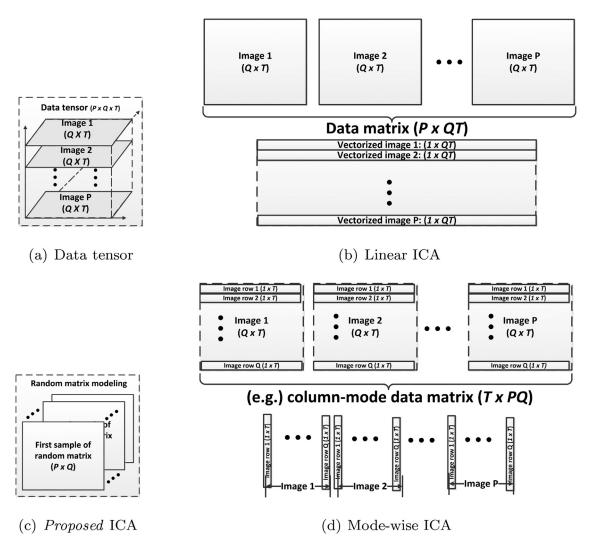

Fig. 1. Given a $P \times Q \times T$ data tensor in (a), classical linear ICA vectorizes each image mixture into a long row vector and stacks them into a $P \times QT$ data matrix as in (b) for source recovery. Mode-wise ICA models, such as DTICA [5.6] and MMICA [7], unfold the data tensor along an image (column or row) mode, to obtain a $T \times PQ$ (or $Q \times PT$) data matrix as in (d), on which to apply classical ICA (twice). The proposed RAMICA model deals with the data tensor directly *without* vectorization or unfolding as in (c).

stacking all data along a particular dimension (the first 'mode' by default). This paper focuses on *ICA for such data tensor input*. For convenience of discussion, we consider stacking *P* 2*D images* of size $Q \times T$ into a third-order *data tensor* of size $P \times Q \times T$. Fig. 1(a) shows the stacking of images into a data tensor.

There are two existing ICA approaches for data tensor input. The first *classical approach* is a linear one, which *vectorizes* (*reshapes*) images into vectors so that we can apply classical ICA methods such as FastICA [9], JADE [10], and Infomax [11]. Equivalently, we can view this *vectorization* process as *unfolding* the data tensor of size $P \times Q \times T$ into a data matrix of size $P \times QT$ along the first mode, as shown in Fig. 1(b). The sources can be recovered as vectors first and then folded (reshaped) back to images (matrices). However, the vectorization breaks the original structure and leads to high-dimensional vectors, imposing significant theoretical and computational challenges. There are some other ICA variations [12–14] where more complicated data inputs are considered (e.g., images with known forming factors), but images are still represented as vectors and they degenerate to classical ICA under basic (simplified) settings [7].

The second approach is to do *mode-wise (linear) ICA* to partially preserve structural information and explore computational benefits (as shown in Fig. 1(d)), where the data tensor is unfolded along each of the original image dimensions (image row or column) into

data matrices of size $Q \times PT$ and $T \times PQ$ to apply classical ICA. This brings an additional issue of mixing modeling, with two ways summarized below.

The first way of modeling in mode-wise ICA is a *multilinearmixing model* as in Directional Tensor ICA (DTICA) [5,6], where an image mixture is generated by *one source matrix* and *two modewise mixing matrices* (one for each mode). DTICA forms row and column directional images by shifting the rows/columns and then estimates two mixing matrices by mode-wise FastICA. Similarly, Virta et al. [15,16] generalize JADE and FOBI [17] to mode-wise versions for data tensor input, using *multiple mode-wise mixing matrices* to mix *one latent tensor*. Such multilinear-mixing models have an inherent limitation. They *cannot do BSS* to recover multiple matrix/tensor sources since they model a single source/tensor matrix only, which is hard to interpret in a BSS context.

The second way of modeling in mode-wise ICA is a *multilinear*source model as in Multilinear Mode-wise ICA (MMICA) [7], where an image mixture is generated by two mode-wise source matrices via a multilinear mixing matrix. This model resembles the mixing model (1) more closely. However, it assumes the sources are rank one and constructed by mode-wise source matrices. Thus, although MMICA can do BSS, it can only recover rank-one sources due to its strong assumptions. This paper proposes a new, third approach for ICA with data tensor input. Different from all existing works, we aim to recover general (not only rank-one) sources as the first approach can do while preserving multidimensional structure as the second approach. We do so by working with the original data tensor *directly* as shown in Fig. 1(c), without vectorization or unfolding. We develop our new method by considering random matrix in modeling so we name it RAndom Matrix ICA (RAMICA). In the RAMICA model, a random matrix consists of multiple random vectors. It assumes that observed image data are generated by mixing source images with row-wise or column-wise structures. We make three major contributions in developing this RAMICA model and deriving the RAMICA algorithm:

- 1. With random matrix modeling, we propose RAMICA, a new ICA approach for data tensor input that deals with data tensor directly without vectorization or unfolding. Thus, RAMICA preserves multidimensional structure and can recover general source matrices in BSS.
- We define new statistics of random matrix including covariance matrix, white matrix, independence, and higher-order cumulants, as the basis to develop RAMICA for data tensor input.
- 3. We formulate the RAMICA objective function by introducing a *whitening* step for a respective *whitened* random matrix and a new *cumulant operator* for random matrices. Then we derive a new RAMICA algorithm to recover source matrices with the Jacobi method.

The rest of the paper is organized as follows. Section 2 offers a brief overview of notations and technical preliminaries. Section 3 formulates the RAMICA model and Section 4 derives the RAMICA algorithms. Section 5 presents futher discussions of the proposed approach. Section 6 reports our numerical studies on both synthetic and real data. Finally, Section 7 draws conclusions.

2. Preliminaries

2.1. Notation

Table 1 lists the symbols used for easy reference. Deterministic variables are in normal fonts, and random variables are underlined. Scalars, vectors, matrices, and tensors are denoted by lowercase, lowercase boldface, uppercase boldface, and bold calligraphic letters, respectively. For example, x, \mathbf{x} , \mathbf{X} , and $\boldsymbol{\mathcal{X}}$ are used to denote deterministic variables, and \underline{x} , $\underline{\mathbf{x}}$, $\underline{\mathbf{X}}$, and $\boldsymbol{\mathcal{X}}$ are used to denote random variables.

2.2. Random vector and cumulants

A random vector is a vector of random variables $\underline{\mathbf{x}} = [\underline{x_1}, \dots, \underline{x_Q}]^{\mathsf{T}}$. Its expectation is a vector $E(\underline{\mathbf{x}}) = [E(\underline{x_1}), \dots, E(\underline{x_Q})]^{\mathsf{T}}$. Its covariance matrix is

$$\Sigma(\underline{\mathbf{x}}) = \begin{bmatrix} \sigma^2(\underline{x_1}) & \cdots & cov(\underline{x_1}, \underline{x_Q}) \\ \vdots & & \vdots \\ cov(\underline{x_Q}, \underline{x_1}) & \cdots & \sigma^2(\underline{x_Q}) \end{bmatrix},$$
(4)

where $cov(\underline{x_i}, \underline{x_j})$ is the covariance of $\underline{x_i}$ and $\underline{x_j}$, and $\sigma^2(\underline{x_i})$ is the variance of $\underline{x_i}$. If $\underline{x_1}, \ldots, \underline{x_Q}$ are mutually independent, $\underline{\mathbf{x}}$ has independent components, and $\Sigma(\underline{\mathbf{x}})$ becomes diagonal. $E(\underline{\mathbf{x}})$ and $\Sigma(\underline{\mathbf{x}})$ are the first and second order *cumulants* of $\underline{\mathbf{x}}$. Higherorder cumulants with order $r \ge 3$ are denoted by $[\mathcal{Q}_r(\underline{\mathbf{x}})]_{i_1\cdots i_r}$ or $cum(x_{i_1}, \ldots, x_{i_r})$, where i_1, \ldots, i_r are the mode-wise indices.

Cumulants of a random vector $\underline{\mathbf{x}}$ have the following four properties:

- symmetry: $[\mathcal{Q}_r(\underline{\mathbf{x}})]_{i_1\cdots i_r} = [\mathcal{Q}_r(\underline{\mathbf{x}})]_{i_{\sigma(1)}\cdots i_{\sigma(r)}}$ for any permutation $\sigma(\cdot)$;
- *linearity*: $cum(\underline{x}_1, \dots, \underline{x}_i + \underline{y}, \dots, \underline{x}_r) = cum(\underline{x}_1, \dots, \underline{x}_i, \dots, \underline{x}_r) + cum(\underline{x}_1, \dots, \underline{y}, \dots, \underline{x}_r)$ and $cum(\underline{x}_1, \dots, \underline{\alpha}, \underline{x}_i, \dots, \underline{x}_r) = \alpha cum(\underline{x}_1, \dots, \underline{x}_i, \dots, \underline{x}_r)$ for any random variable *y* and deterministic α ;
- *independence*: if $\exists p, q \in \{1, ..., r\}$ where $\underline{x_{i_p}}$ and $\underline{x_{i_q}}$ are independent, then $[\mathcal{Q}_r(\underline{\mathbf{x}})]_{i_1 \cdots i_r} = 0$;
- vanishing Gaussian: if x is Gaussian, [Q_r(x)]_{i1···ir} = 0 for any order r ≥ 3.
- 2.3. ICA steps and tensor mode-1 product

ICA has three standard steps, as explained in this subsection.

- 1. *Centering*: remove the first-order statistics from the data by shifting the sample mean to the origin.
- Whitening: remove the second-order statistics from the data to obtain whitened variables. Here, the second-order statistics and the whitening process need to be redefined for the proposed model.
- IC Estimation: use higher-order statistics of the data to estimate ICs. It is the core step of ICA, and different methods do it differently.

The mode-1 product of a third-order tensor $\mathcal{A} \in \mathbb{R}^{l_1 \times l_2 \times l_3}$ by a matrix $\mathbf{U} \in \mathbb{R}^{l_n \times l_n}$, denoted by $\mathcal{A} \times_1 \mathbf{U}$, is a tensor with entries [18,19]:

$$(\mathcal{A} \times_1 \mathbf{U})_{j_1 i_2 i_3} = \sum_{i_1} \mathcal{A}_{i_1 i_2 i_3} \cdot \mathbf{U}_{j_1 i_1}.$$
(5)

3. A random matrix model for ICA

3.1. RAMICA model and assumptions

First, we view ICA from a random matrix perspective. A *random matrix* is a matrix of random variables $\underline{\mathbf{X}} = [\underline{x_{ij}}] \in \mathbb{R}^{P \times Q}$ and its expectation matrix is $E(\underline{\mathbf{X}}) = [E(\underline{x_{ij}})] \in \mathbb{R}^{P \times Q}$. Traditionally, its covariance matrix is defined as

$$\Sigma(\underline{\mathbf{X}}) := \Sigma(\operatorname{vec}(\underline{\mathbf{X}})) \in \mathbb{R}^{(PQ) \times (PQ)},\tag{6}$$

where $vec(\cdot)$ is the vectorization operator [20–22], and its higherorder cumulants are defined via vectorizing the random matrix to the random vector. Thus, the independence of random matrix involves the independence of all elements. Equivalently, these definitions treat random matrix as its vectorized version, without considering any structural information.

Here, we follow (1), (2), and (3) in classical ICA. Instead of (1), we have *M* mixtures $\underline{\mathbf{x}}_1, \ldots, \underline{\mathbf{x}}_M \in \mathbb{R}^Q$ of *P* random vector sources (ICs) as:

$$\mathbf{x}_m = a_{m1}\mathbf{s}_1 + \dots + a_{mP}\mathbf{s}_P,\tag{7}$$

where $\mathbf{x}_{\underline{m}}$ is the *m*th mixture random vector, $\mathbf{s}_1, \ldots, \mathbf{s}_P$ are the independent source random vectors, and a_{m1}, \ldots, a_{mP} are mixing coefficients (see Fig. 1(c)). Again, we assume M = P. Stacking *P* random vectors $\{\mathbf{x}_{\underline{m}}\}$ and $\{\mathbf{s}_{\underline{p}}\}$ into random matrices along the first mode, we obtain the *observation (mixture) matrix* $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_P]^\top \in \mathbb{R}^{P \times Q}$, and the source matrix $\mathbf{S} = [\mathbf{s}_1, \ldots, \mathbf{s}_P]^\top \in \mathbb{R}^{P \times Q}$ respectively. We have the full matrix notation version of (7) instead of (2) below:

$$\underline{\mathbf{X}} = \mathbf{A}\underline{\mathbf{S}},\tag{8}$$

where $\mathbf{A} \in \mathbb{R}^{P \times P}$ is the *mixing matrix* and assumed to be full-rank. With *T* samples of such *random matrices*, we form the data tensor \mathcal{X} and source tensor \mathcal{S} of size $P \times Q \times T$. Then we can write

RAMICA model in data tensors \mathcal{X} and \mathcal{S} instead of (3) as

$$\boldsymbol{\mathcal{X}} = \boldsymbol{\mathcal{S}} \times_1 \mathbf{A},\tag{9}$$

where \times_1 denotes the mode-1 multiplication of a tensor by a matrix as defined in (5). We can view (9) as a *partial* Tucker decomposition [23].

The RAMICA objective is to estimate the source tensor S and mixing matrix **A** given the data tensor \mathcal{X} only. Fig. 1(c) shows this RAMICA model for data tensor, which is viewed along the third mode (instead of the first mode of stacking as shown in Fig. 1(a)) as *T* samples of the random matrix **X**, i.e. **X**(1), ..., **X**(*T*).

Remark. Note that (7), (8), and (9) in RAMICA correspond to (1), (2), and (3) in classical ICA, respectively. When Q = 1, the RAMICA model degenerates to the classical ICA model. Thus, RAM-ICA is a natural second-order generalization of classical ICA, without vectorization or unfolding. A key difference between (7) and (1) is that while $\mathbf{s}_1, \ldots, \mathbf{s}_p$ are independent, the components of each source random vector \mathbf{s}_p can be dependent and encode structural information. This allows structural information to be better preserved in RAMICA than in classical ICA.

To derive RAMICA algorithm, we make three assumptions analogous to classical ICA [24]:

- 1. The expectation of mixture or source matrix is zero, i.e. $E(\underline{S}) = E(\underline{X}) = \mathbf{0}_{P \times Q}$. A *centering* process will be performed if the input data are not centered.
- The covariance matrix of the source random matrix is an identity matrix. Note the definition in (6) is equivalent to vectorizing <u>X</u>, leading to the first, vectorization-based ICA approach. Thus, we need *new definitions of related statistics for random matrix* to embody structural information.
- 3. At most one independent random vector from $\{\underline{s}_p\}$ has multivariate Gaussian distribution.

3.2. New statistics of random matrix

We define new statistics for RAMICA via *tensor contraction*. On its basis, we subsequently define the *white* random matrix and the whitened RAMICA model.

Definition 1. The **contracted covariance matrix** of a zero-mean random matrix $\underline{\mathbf{X}} = [\mathbf{x}_1, \dots, \mathbf{x}_P]^\top \in \mathbb{R}^{P \times Q}$ is defined as:

$$\widetilde{\Sigma}(\underline{\mathbf{X}}) = \frac{1}{Q} E[\underline{\mathbf{X}} \underline{\mathbf{X}}^{\top}] \in \mathbb{R}^{P \times P}.$$
(10)

Each element of $\widetilde{\Sigma}(\underline{X})$ is the covariance of two corresponding random vectors:

$$[\widetilde{\Sigma}(\underline{\mathbf{X}})]_{ij} = \widetilde{cov}(\underline{\mathbf{x}}_i, \underline{\mathbf{x}}_j) = \frac{1}{Q} \sum_{q=1}^{Q} cov(\underline{x}_{iq}, \underline{x}_{jq}),$$
(11)

where $cov(\cdot, \cdot)$ is the conventional covariance.

Definition 2. Given a zero-mean random matrix $\underline{\mathbf{X}} = [\underline{\mathbf{x}_1}, \dots, \underline{\mathbf{x}_P}]^\top \in \mathbb{R}^{P \times Q}$, its **contracted cumulant** of order $r \ge 3$ denoted by $[\widetilde{Q_r}(\underline{\mathbf{X}})]_{i_1 \cdots i_r}$ or $\widetilde{cum}(\mathbf{x}_{i_1}, \dots, \underline{\mathbf{x}_{i_r}})$ is defined as:

$$[\widetilde{\mathcal{Q}}_{r}(\underline{\mathbf{X}})]_{i_{1}\cdots i_{r}} = \frac{1}{Q} \sum_{q=1}^{Q} cum(\underline{x_{i_{1}q}}, \dots, \underline{x_{i_{r}q}}),$$
(12)

where $i_1, \ldots, i_r \in \{1, \ldots, P\}$, and $cum(\cdot)$ is the conventional cumulant of a random vector. In particular, we denote a special case

$$\mathcal{K}_{r}(\underline{\mathbf{x}_{p}}) = \widetilde{cum}(\underbrace{\mathbf{x}_{p}, \dots, \mathbf{x}_{p}}_{(r \text{ times})}).$$
(13)

Lemma 1. The newly defined cumulants for random matrix $\underline{\mathbf{X}} = [\underline{\mathbf{x}}_1, \dots, \underline{\mathbf{x}}_P]^\top \in \mathbb{R}^{P \times Q}$ satisfies the properties of conventional cumulants for random vectors: (1) symmetry, (2) linearity, (3) independence, and (4) vanishing Gaussian.

Proof. This lemma can be obtained by using the corresponding properties of cumulants for random vector in Section 2.2 multiple times and do a final average operation as denoted in (12). \Box

Definition 3. A random matrix $\underline{\mathbf{X}} = [\underline{\mathbf{x}_1}, \dots, \underline{\mathbf{x}_P}]^\top \in \mathbb{R}^{P \times Q}$ is **independent** if the conditional distribution of $\underline{\mathbf{x}_i}$ given $\underline{\mathbf{x}_j} = \mathbf{x}$ does not depend on \mathbf{x}_i (i.e. \mathbf{x}_i and \mathbf{x}_j are mutually independent):

$$f_{\mathbf{x}_i|\mathbf{x}_j}(\underline{\mathbf{x}_i}|\mathbf{x}_j) = f_{\underline{\mathbf{x}}_i}(\underline{\mathbf{x}}_i).$$
(14)

Using these new statistics defined for random matrix, we can derive our RAMICA algorithm.

3.3. Alternative forms of the RAMICA model

Given *P* images of size $R \times C$ (*R* rows and *C* columns), we can form a data tensor $\mathcal{X} \in \mathbb{R}^{P \times Q \times T}$ in (9) in two ways:

- *Row-wise* RAMICA (**rRAMICA**): each image row is treated as a random vector in \mathbb{R}^C and all the *R* rows are considered *R* samples of this random vector so Q = C and T = R.
- Column-wise RAMICA (**cRAMICA**): each image column is treated as a random vector in \mathbb{R}^R and all the *C* columns are considered *C* samples of this random vector so Q = R and T = C.

Thus, rRAMICA and cRAMICA consider row and column structural information of image data, respectively. Real-world image data often have structures in both rows and columns so both rRAMICA and cRAMICA can be effective. For example, in the real image BSS experiments in Section 6.2, we know *both* row and column structures present in most real images and the results in Fig. 3(b) indeed show that *both* versions lead to improvement in the noiseless and low noise settings.

These two versions of RAMICA capture different aspects of data, which can offer alternative explanations of the data. If we use RAMICA as a feature extractor, we can combine both versions to provide complementary features.

If we have to choose one from the two, a *model selection* problem arises. We can consider this choice as a hyper-parameter and determine it based on prior knowledge of the data, cross validation, or other statistical model selection strategies, e.g., picking the one with a higher kurtosis.

For convenience of discussion, when we talk about RAMICA, we refer to **cRAMICA** unless specified explicitly.

4. The RAMICA algorithm

Given zero-mean input, the RAMICA algorithm has two steps, i.e., whitening and IC estimation.

4.1. RAMICA whitening

Definition 4. A random matrix $\underline{\mathbf{X}} = [\underline{\mathbf{x}}_1, \dots, \underline{\mathbf{x}}_P]^\top \in \mathbb{R}^{P \times Q}$ is **contracted white** if its covariance matrix is an identity matrix:

$$\widetilde{\Sigma}(\mathbf{X}) = \mathbf{I}_{P \times P}.\tag{15}$$

Therefore, the **contracted whitening** step of the RAMICA model (8) is to find a matrix **W** such that $\widetilde{\Sigma}(\mathbf{WX}) = \mathbf{I}_{P \times P}$.

Theorem 1. For the RAMICA model (8), let **W** denote any inverse square root of $\tilde{\Sigma}(\underline{\mathbf{X}})$, i.e. $[\tilde{\Sigma}(\underline{\mathbf{X}})]^{-1/2}$. **W** is the whitening matrix and **W** $\underline{\mathbf{X}}$ is white. Literally, any square-root of the covariance matrix is a whitening matrix.

Proof. Perform Singular Value Decomposition (SVD) on the mixing matrix $\mathbf{A} = \mathbf{EDV}$, where \mathbf{E} and \mathbf{V} are orthogonal, and \mathbf{D} is diagonal.

Compute the covariance matrix of $\underline{\mathbf{X}}$ using the above decomposition:

$$\widetilde{\Sigma}(\underline{\mathbf{X}}) = \frac{1}{Q} E[\mathbf{E}\mathbf{D}\mathbf{V}\mathbf{S}\mathbf{S}^{\mathsf{T}}\mathbf{V}^{\mathsf{T}}\mathbf{D}\mathbf{E}^{\mathsf{T}}] = \mathbf{E}\mathbf{D}^{2}\mathbf{E}^{\mathsf{T}}.$$
(16)

The second equality is due to *Assumption 2* of RAMICA and the orthogonality of **V**. Denote by $\mathbf{M} \in \mathbb{R}^{P \times P}$ any *orthogonal* matrix, then according to Ilmonen et al. [25], **W** can be written as:

$$\mathbf{W} = \mathbf{M}\mathbf{D}^{-1}\mathbf{E}^{\top} \in \mathbb{R}^{P \times P}.$$
(17)

Next, we calculate the covariance matrix of WX as

$$\widetilde{\Sigma} (\mathbf{W} \underline{\mathbf{X}}) = \frac{1}{Q} E[\mathbf{M} \mathbf{D}^{-1} \mathbf{E}^T \underline{\mathbf{X}} \underline{\mathbf{X}}^\top \mathbf{E} \mathbf{D}^{-1} \mathbf{M}^\top]$$

$$= \mathbf{M} \mathbf{D}^{-1} \mathbf{E}^\top [\Sigma (\underline{\mathbf{X}})] \mathbf{E} \mathbf{D}^{-1} \mathbf{M}^\top$$

$$= \mathbf{M} \mathbf{D}^{-1} \mathbf{E}^\top [\mathbf{E} \mathbf{D}^2 \mathbf{E}^\top] \mathbf{E} \mathbf{D}^{-1} \mathbf{M}^\top$$

$$= \mathbf{I}_{P \times P}.$$
(18)

Therefore, we have proved that $\mathbf{W}\underline{\mathbf{X}}$ is white and \mathbf{W} is the whitening matrix. \Box

Similar to classical ICA, we can conduct eigenvalue decomposition on the covariance matrix as

$$\widetilde{\Sigma}(\underline{\mathbf{X}}) = \mathbf{E} \mathbf{\Lambda} \mathbf{E}^{\mathsf{T}},\tag{19}$$

where $\mathbf{E} = [\mathbf{e}_1, \dots, \mathbf{e}_P]$ has the unit-norm eigenvectors as columns, and the diagonal matrix $\mathbf{\Lambda}$ consists of the eigenvalues. According to Theorem 1, the whitening matrix is

$$\mathbf{W} = \mathbf{\Lambda}^{-1/2} \mathbf{E}^{\mathsf{T}}.$$
 (20)

After RAMICA whitening, we have $\mathbf{W}\underline{\mathbf{X}} = \mathbf{W}\mathbf{A}\underline{\mathbf{S}} = \mathbf{U}\underline{\mathbf{S}}$. Since $\widetilde{\Sigma}(\mathbf{W}\underline{\mathbf{X}}) = \mathbf{I}_{P \times P} = \mathbf{U}\widetilde{\Sigma}(\underline{\mathbf{S}})\mathbf{U}^{\top} = \mathbf{U}\mathbf{U}^{\top}$, **U** is orthogonal. The *whitened RAMICA* model can be rewritten as

$$\widehat{\mathbf{X}} = \mathbf{U}\underline{\mathbf{S}},\tag{21}$$

where $\hat{\mathbf{X}}$ is the whitened random matrix and \mathbf{U} is the whitened mixing matrix.

Lemma 2. Given the whitened RAMICA model (21), the fourth-order cumulants of (whitened) $\hat{\mathbf{X}}$ satisfy:

$$[\widetilde{\mathcal{Q}}_4(\widehat{\mathbf{X}})]_{ijkl} = \sum_p u_{ip} u_{jp} u_{kp} u_{lp} \mathcal{K}_4(\underline{\mathbf{s}}_p), \quad \forall i, j, k, l \in \{1, \dots, P\}.$$
(22)

Proof. Calculate the fourth-order cumulants according to Lemma 1. We have:

$$[\widetilde{\mathcal{Q}}_{4}(\widehat{\mathbf{X}})]_{ijkl} = cum(\sum_{p} u_{ip} \underline{\mathbf{s}}_{\underline{p}}, \sum_{p'} u_{jp'} \underline{\mathbf{s}}_{\underline{p}'}, \sum_{q} u_{kq} \underline{\mathbf{s}}_{\underline{q}}, \sum_{q'} u_{lq'} \underline{\mathbf{s}}_{\underline{q}'})$$
$$= \sum_{p,p',q,q'} u_{ip} u_{jp'} u_{kq} u_{lq'} cum(\underline{\mathbf{s}}_{\underline{p}}, \underline{\mathbf{s}}_{\underline{p}'}, \underline{\mathbf{s}}_{\underline{q}}, \underline{\mathbf{s}}_{\underline{q}'}).$$
(23)

Due to the independence of $\{\widehat{\mathbf{s}}_p\}$, only those products with p = p' = q = q' are nonzero. Therefore, we have proved that

$$[\widetilde{\mathcal{Q}}_{4}(\widehat{\mathbf{X}})]_{ijkl} = \sum_{p} u_{ip} u_{jp} u_{kp} u_{lp} \mathcal{K}_{4}(\underline{\mathbf{s}}_{p}).$$
(24)

4.2. RAMICA IC estimation

It is difficult to recover sources directly from cumulants. Instead, we can convert the BSS problem to a matrix diagonalization problem as in JADE [10], via a cumulant-based mapping of the whitened mixing matrix **U**. To do this, we firstly define a new cumulant operator.

Definition 5. Given the whitened RAMICA model (21), the **cumulant operator** $\mathscr{F}_{\widehat{\mathbf{X}}}$ is defined by the fourth-order cumulant tensor $\widetilde{\mathcal{Q}_4}(\widehat{\mathbf{X}})$ of random matrix $\widehat{\mathbf{X}}$ as:

$$\mathscr{F}_{\widehat{\mathbf{X}}}:\mathbf{M}\in\mathbb{R}^{P\times P}\mapsto[\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})]_{ij}=\sum_{k,l}m_{kl}[\widetilde{\mathcal{Q}}_{4}(\widehat{\mathbf{X}})]_{ijkl}\in\mathbb{R}^{P\times P}.$$
(25)

Lemma 3. Given the whitened RAMICA model (21), the cumulant operator $\mathscr{F}_{\widehat{\mathbf{X}}}$ satisfies:

$$[\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})]_{ij} = \sum_{p} u_{ip} u_{jp} \mathcal{K}_4(\underline{\mathbf{s}_p}) \sum_{k,l} m_{kl} u_{kp} u_{lp}, \ \forall i, j \in \{1, \dots, P\}.$$
(26)

Proof. This lemma can be proved by substituting cumulants $[\mathcal{Q}_4(\widehat{\mathbf{X}})]_{ijkl}$ in (25) by the derived (22) of Lemma 2. \Box

Theorem 2. Given the whitened model (21), the matrix $[\mathbf{U}^{\top} \mathscr{F}(\mathbf{M})\mathbf{U}]$ is diagonal for $\forall \mathbf{M} \in \mathbb{R}^{P \times P}$.

Proof. According to matrix multiplication rules and Lemma 3, we know for $\forall i, j \in \{1, ..., P\}$:

$$[\mathbf{U}^{\top} \mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})\mathbf{U}]_{ij} = \sum_{p,q} u_{pi}u_{qj} [\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})]_{pq}$$
(27)
$$= \sum_{p,q} u_{pi}u_{qj} \sum_{m} u_{pm}u_{qm}\mathcal{K}_{4}(\underline{\mathbf{s}}_{\underline{m}}) \sum_{k,l} m_{kl}u_{km}u_{lm}$$
$$= \sum_{m} \mathcal{K}_{4}(\underline{\mathbf{s}}_{\underline{m}}) \sum_{k,l} m_{kl}u_{km}u_{lm} \sum_{p} u_{pi}u_{pm} \sum_{q} u_{qj}u_{qm}.$$

Since **U** is orthogonal, we have

$$[\mathbf{U}^{\top}\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})\mathbf{U}]_{ij} = \sum_{m} \mathcal{K}_{4}(\underline{\mathbf{s}_{m}}) \sum_{k,l} m_{kl} u_{km} u_{lm} \delta_{im} \delta_{jm}.$$
 (28)

Only those products with i = j = m are nonzero. Thus, we have

$$\left[\mathbf{U}^{\top}\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})\mathbf{U}\right]_{ij} = \begin{cases} 0, & \text{if } i \neq j \\ \mathcal{K}_4(\underline{\mathbf{s}}_i) \sum_{k,l} m_{kl} u_{ki} u_{li}, & \text{if } i = j. \end{cases}$$
(29)

Therefore, we have proved the diagonality of $\mathbf{U}^{\top} \mathscr{F}(\mathbf{M}) \mathbf{U}$. \Box

4.3. RAMICA objective

Theorem 2 reveals the connection between the whitened RAM-ICA model (21) and $\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})$. We can take a set of matrices \mathbf{M}_i and make the matrix set $\{\mathbf{U}^\top \mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M}_i)\mathbf{U}\}$ as diagonal as possible for BSS. In practice, they cannot be made exactly diagonal because the model does not hold exactly and there are sampling errors. In fact, the diagonality of a symmetric matrix $\mathbf{Q} = \mathbf{U}^\top \mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})\mathbf{U}$ can be measured by the sum of the squares of off-diagonal entries: $\sum_{i\neq j} q_{ij}^2$ [26]. Since for a given matrix $\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M})$, the square sum over all elements of the matrix is preserved under an orthogonal transformation, minimizing the sum of squares of off-diagonal elements is equivalent to maximizing the sum of squares of diagonal elements [27]. We formulate our objective function based on this property. For a set of basis matrix $\{\mathbf{M}_i \in \mathbb{R}^{P \times P}\}$, we maximize the following objective function with respect to orthogonal matrix \mathbf{U} :

$$\sum_{i} ||\operatorname{diag}(\mathbf{U}^{\top}\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{M}_{i})\mathbf{U})||^{2},$$
(30)

where $||\text{diag}(\cdot)||^2$ denotes the sum of squares of the diagonal elements. In this paper, we use the standard basis of $\mathbb{R}^{P \times P}$, i.e. { $\mathbf{E}^{ij} = \mathbf{e}_i \mathbf{e}_i^\top$ }, which can reduce computational cost significantly.

4.4. RAMICA optimization

Similar to JADE, we apply Jacobi method to optimize (30) to compute the whitened mixing matrix **U**. To use the Jacobi method, we first align the set of matrices $\{\mathscr{F}(\mathbf{E}^{ij})\}_{i,j=1}^{p}$ into an extended matrix $\mathbf{M} = [\mathscr{F}(\mathbf{E}^{11}), \ldots, \mathscr{F}(\mathbf{E}^{PP})]$. Then, we apply the Jacobi method on **M** to conduct a series of Jacobi rotations, each of which handles two rows and two columns at a time [28]. After this, we obtain \mathbf{U}^{-1} by multiplying the rotation matrices. Subsequently, we get **A** from $\mathbf{A}^{-1} = \mathbf{U}^{-1}\mathbf{W}$. The RAMICA algorithm is

Algorithm 1 Random Matrix Modeling ICA (RAMICA).

- Input: a zero-mean data tensor *X* ∈ ℝ^{P×Q×T}. The last dimension contains the samples.
- 2: **Contracted whitening**: viewing \mathcal{X} as T samples of \underline{X} , compute the sample estimate of the whitening matrix \mathbf{W} according to Theorem 1, and compute the whitened data tensor: $\mathcal{X} \times_1 \mathbf{W}$.
- 3: Construct the contracted cumulant tensor by (12).
- 4: Construct cumulant matrices $\{\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{E}^{ij})\}\$ according to (25) for $\forall i, j \in \{1, \dots P\}$.
- 5: Align the above matrices to form the matrix $\mathbf{M} = [\mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{E}^{11}), \dots, \mathscr{F}_{\widehat{\mathbf{X}}}(\mathbf{E}^{PP})].$
- 6: Apply Jacobi method to **M** to get rotation matrices.
- 7: Get \mathbf{U}^{-1} by multiplying the rotation matrices.
- 8: Compute $\mathbf{A}^{-1} = \mathbf{U}^{-1}\mathbf{W}$, and $\mathbf{A} = (\mathbf{A}^{-1})^{-1}$. 9: Compute $S = \mathcal{X} \times \mathbf{A}^{-1}$.
- 10: **Output:** mixing matrix **A** and source tensor S.

summarized in Algorithm 1, where we view \mathcal{X} as T samples of $\underline{\mathbf{X}}$ to obtain sample-based estimates of various statistics. The theoretical properties of the newly defined cumulant can be extended to such empirical estimations following [24, §2.7].

5. Discussions

5.1. Identifiability and uniqueness

In our RAMICA formulation, the mixing matrix **A** in (8) plays exactly the same role as the mixing matrix **A** in (2) of classical ICA. The cumulant operator in Definition 5 maps the fourth-order cumulants of (whitened) mixture $\hat{\mathbf{X}}$ to a $P \times P$ matrix in (5). This contraction operates on the tensor observation data to reduce the RAMICA problem to JADE. Thus, the RAMICA objective function (30) is similar to the objective function in JADE [10] and theoretical results on JADE can be similarly applied here.

Miettinen et al. [29] have proved that the joint diagonalization procedure achieves mixing matrix recovery for the identifiable case of at most one Gaussian source in Theorems 8 and 9 of their paper. These theorems help establish that the same joint diagonalization procedure in our proposed RAMICA can recover the mixing matrix when there is at most one Gaussian source and the contraction operation via $\widetilde{\mathcal{Q}_4}(\cdot)$ does not lead to an ICA instance with all Gaussian sources.

Note however that the mixing matrix can be identified only up to the order and signs (independent components are not ordered as in principal components). Therefore, if $V^{\top}\mathscr{F}_{\widehat{X}}(M_i)V$ is diagonal for all M under the RAMICA formulation, we will get a V that is equivalent to U only up to the order (permutation) and signs.

5.2. Higher-order extensions

RAMICA can be extended to higher-order tensors by extending *random matrix modeling* to *random tensor modeling*, and tensor contraction over *one* mode to over *multiple* modes. For instance, given a fourth order tensor $\widetilde{\mathcal{X}}$ of size $P \times Q \times R \times T$ formed by stacking *P* tensors of size $Q \times R \times T$, the mixing model in (7) can be extended to M = P mixtures $\underline{\mathbf{X}}_1, \ldots, \underline{\mathbf{X}}_M \in \mathbb{R}^{Q \times R}$ of *P* random matrix sources (ICs) as:

$$\mathbf{X}_{\underline{m}} = a_{m1}\mathbf{S}_{\underline{1}} + \dots + a_{mP}\mathbf{S}_{\underline{P}}.$$
(31)

Respectively, (8) becomes

$$\underline{\mathcal{X}} = \underline{\mathcal{S}} \times_1 \mathbf{A}. \tag{32}$$

We can then view \tilde{X} as *T* samples of *random tensors* with size $P \times Q \times R$. We can subsequently define mode-wise covariance matrices and cumulant for mode 1, now with summation over *Q* and *R* instead of just *Q*. Given *P* third-order tensors, we will have three (instead of two) ways of forming a fourth-order data tensor: i.e., treating its mode-*n* slice ($n \in \{2, 3, 4\}$) as a random matrix. Further extensions (e.g., to fifth-order tensor of $P \times Q \times R \times S \times T$) can be similarly formulated.

5.3. Relationship to existing methods

5.3.1. Differences with existing tensor-based ICA

In terms of source separation, RAMICA captures structural information better than classical ICA, and lifts the restriction of rankone sources in MMICA, while being superior over DTICA's single source assumption that is hard to interpret and unable to do source separation.

5.3.2. Connection to ISA

Independent Subspace Analysis (ISA) [30,31], a.k.a. group ICA or subspace ICA, is a generalization of ICA, which assumes some random (scalar) sources are mutually dependent, but the dependencies among the sources of different groups are minimized. In this sense, it shares similarity with RAMICA by viewing these dependent sources as random vector sources. However, the ways of RAMICA and ISA in modeling and solving the problems are essentially different. ISA arises from the relaxation of ICA assumptions by restricting its mixing matrix, and is often solved by first preprocessing the mixtures by an classical ICA algorithm and then grouping the estimated components with highest dependence. In contrast, RAMICA is a generalization of classical ICA designed from a random matrix formulation with a natural interpretation and our mixing matrix is general, as in the classical ICA.

5.3.3. Connection to IVA

Independent Vector Analysis (IVA) [32,33] is another generalization of ICA to multiple datasets. IVA takes *K* data matrices as input and assumes that the *k*th data matrix is obtained by linearly mixing rows of the *k*th source matrix through the *k*th mixing matrix. Thus, there are *K* related ICA problems. IVA and RAMICA both take multiple data matrices as the input and make similar independence assumptions. However, IVA considers each data matrix as a dataset but RAMICA considers it as a sample of a dataset. Therefore, IVA estimates *K* mixing matrices but RAMICA estimates *only one* mixing matrix. RAMICA can be extended to deal with multiple matrix/tensor datasets following IVA.

5.4. Potential significance of RAMICA

Direct ICA on data tensor is a technically challenging problem without much success before this work. RAMICA provides theoretical/conceptual contributions in overcoming the technical challenges in a tensor-based ICA without unfolding, including a new random matrix modeling approach for ICA and new statistics for random matrix. This enables further development of robust variants and higher-order extensions, as sketched above. Its connection with ISA discussed above also sheds new light on ICA research. Thus, the significance of such contributions may go beyond ICA/BSS and impact not only ICA, but also more general tensor-based learning (without unfolding) and random-matrix-based machine learning. Although we showed only separation of real images below, RAMICA is promising in solving practical neuroimaging problems such as for EEG and fMRI, where ICA is very popular [34–36].

6. Numerical results

In this section, we perform evaluations on BSS with data tensor input for sources having general 2D structures, rather than special structures such as rank one. We compare two versions of RAMICA, i.e. rRAMICA and cRAMICA, against classical ICA methods FastICA,² JADE,³ and Infomax⁴ with default settings. The implementation of RAMICA in MATLAB has been released at https: //github.com/sunnysong14/ICA-RAMICA. The mode-wise ICA with a *multilinear-mixing model* (DTICA) cannot do BSS because it assumes only one source matrix, while the one with a *multilinearsource model* (MMICA) can only recover rank-one sources by design. Therefore, both DTICA and MMICA will fail on this more general setting of BSS with data tensor input.

BSS experiments were conducted on both synthetic and real data. For synthetic data, we generate *column-wise* source random vectors for mixing. With only column structural information synthesized, we expect cRAMICA to perform well whereas rRAMICA not. For real data, we linearly mix natural images and then recover them from their mixtures. Natural images are expected to have both row and column structural information. Hence, both rRAMICA and cRAMICA are expected to recover the sources to some extent. Which one does better could depend on whether row or column structure is stronger.

For BSS performance measurement, we use the popular Amari error [37] calculated over the demixing matrices (i.e., the inverse of the mixing matrices). For convenience, we report Amari error values multiplied by 100 throughout this paper. We report the average performance with standard deviations (std) over 100 repetitions for each experimental setting below.

6.1. Blind source separation on synthetic data

We first study how well RAMICA can recover sources from synthetic data tensor generated according to the column-wise RAMICA model (9).

6.1.1. Data generation

To simulate *column-wise* structural information in each random vector $\underline{s} \in \mathbb{R}^Q$, only its first component $\underline{s_1}$ is randomly generated, while its other components have the following linear relationships with s_1 :

$$s_q = \alpha s_1 + \beta (q-1), \tag{33}$$

where $\alpha \sim \mathcal{N}(1, 1)$ (Gaussian distribution) and $\beta \sim U(0, 1)$ (uniform distribution) are randomly generated, and $q \in \{2, ..., Q\}$. Thus, $\{\underline{s_1}, \ldots, \underline{s_Q}\}$ are dependent rather than independent and \underline{s} is a column random vector with column structures. We consider the following four distributions that generate the first component of each source random vector $\mathbf{s}_p \in \mathbb{R}^Q$ for $p \in \{1, \ldots, P\}$:

- *Psn*: Pearson distribution with zero mean, unit variance, unit skewness, and unit kurtosis.
- *Stu*: Student-*t* distribution with 5 freedom degrees.
- *Exp*: Exponential distribution with $\lambda = 1$.
- *Lap*: Laplace distribution with $\mu = 0$ and $b = 1/\sqrt{2}$.

Following the above generation, *T* samples of the *p*th random vector \underline{s}_p form the *p*th source image $\mathbf{S}_p = [\mathbf{s}_p(1), \dots, \mathbf{s}_p(T)] \in \mathbb{R}^{Q \times T}$. Finally, stacking *P* source images along the first mode, we have the source tensor $S = [\mathbf{S}_1; \dots; \mathbf{S}_p] \in \mathbb{R}^{P \times Q \times T}$. Such sources are much more realistic/general than the restricted rank-one sources synthesized in MMICA [7]. Note although rank-one sources can be combined to produce low-rank (or high-rank) sources, there is great indeterminacy.

In generating the mixing matrix **A**, we need to guarantee its invertibility. We generate **A** in three steps: (i) uniformly generate a $P \times P$ matrix with each entry between zero and one; (ii) normalize the generated matrix by column; (iii) add an identity matrix to the one in (ii). With *S* and **A** generated, we further generate \mathcal{X} according to (9).

Fig. 2. Illustration of blind source separation on synthetic data with column structures. The illustration opts for the default design factors except that the number of sources is 2 for easier visualization. Specifically, the first component of each source is generated by Student-*t* distribution with 5 degrees of freedom (*Stu*), the dimension of the source random vectors is 32, and the number of random samples is 64.

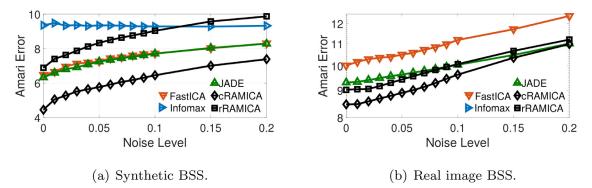

Fig. 3. Effect of the noise level σ^2 for synthetic and real image BSS. Other factors for synthetic BSS use default settings. There are four 256 × 256 source images in the image BSS experiment. The average Amari errors over 100 repetitions are reported. The Infomax results in the image BSS are higher than the chosen upper limit so they are not visible.

6.1.2. Design factors

In simulations, we have the following design factors investigated with several choices:

- $\mathcal{D} \in \{Psn, Stu, Exp, Lap\}$: the distribution used to generate the (first components of) sources.
- $P \in \{2, 4, 8, 16\}$: the number of sources.
- $Q \in \{16, 32, 64, 128\}$: the dimension of the source random vectors.
- $T \in \{16, 32, 64, 128\}$: the number of random samples.
- $\sigma^2 \in \{0, 0.01, 0.02, \dots, 0.1, 0.15, 0.2\}$: the Gaussian noise level that is added to the observation as:

$$\mathbf{X} = \mathbf{A}\mathbf{S} + \mathbf{E},\tag{34}$$

where **<u>E</u>** denotes standard Gaussian noise $vec(\underline{E}) \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$. The default setting is noise-free.

When studying one factor, we vary it with other factors fixed to their default settings in bold above.

6.1.3. Results on synthetic data

Fig. 2 depicts experimental results on synthetic sources with column structures. We show two synthetic source images with strong column structures in Fig. 2(a). Their mixtures are omitted

Table 2

Effect of the underlying source distribution \mathcal{D} for synthetic BSS. Other factors use default settings. Amari errors are reported and each entry is the mean \pm std of 100 repetitions. The best (second-best) Amari errors are highlighted in **bold** (<u>underline</u>).

\mathcal{D}	Infomax	FastICA	JADE	cRAMICA	rRAMICA
Psn	10.03±1.71	$7.07{\pm}1.47$	<u>6.90±1.61</u>	5.12±2.11	7.63±1.23
Stu	$9.35 {\pm} 1.48$	6.48 ± 1.41	6.33 ± 1.44	4.45±2.09	$6.88 {\pm} 1.39$
Ехр	$9.04{\pm}1.50$	6.03 ± 1.22	<u>5.93±1.19</u>	3.72±1.73	6.73 ± 1.24
Lap	$9.29{\pm}1.44$	$6.37 {\pm} 1.42$	<u>6.22</u> ± <u>1.37</u>	$\textbf{4.12{\pm}1.82}$	$6.60 {\pm} 1.19$

in this figure for a neater presentation. We highlight some column structures using red boxes to facilitate observing their recovery visually. We show the BSS results of FastICA, JADE, Infomax, cRAMICA and rRAMICA in Fig. 2(b)–(f), respectively. We can see that cRAMICA can recover column structures better than classical linear ICA algorithms, e.g., FastICA cannot recover the second synthetic source well (the middle red box). As expected, rRAMICA can not do the separation for such strong column structures.

Next, we study the performance of synthetic data separation in a more systematical way. Tables 2–5 report the performance with varying D, P, Q and T, respectively. When varying one factor, de-

fault settings were applied for other factors. The effect of each factor are summarized below.

Effect of D. From Table 2, almost all of the methods get the best results on *Exp* but the worst results on *Psn*, indicating *Psn* is more challenging than *Exp*. Among the five ICA methods, cRAMICA consistently achieves the best performance, though this is expected due to the *column-wise* data tensor generation. In particular, cRAM-ICA improves over JADE (the second best) by 31.4% on average. On the other hand, it is not surprising that rRAMICA gives poorer results. Nonetheless, real-world data often have both row-wise and column-wise structures so both rRAMICA and cRAMICA can be effective and reveal different aspects of data. This will be confirmed in the real data experiments.

Effect of *P*. From Table 3, cRAMICA consistently achieves the best performance and outperforms others by a large margin. For example, cRAMICA outperforms JADE by 29.70% for P = 4. rRAMICA is inferior to cRAMICA, but it outperforms Infomax.

Effect of *Q*. In Table 4, classical ICA methods perform differently with respect to *Q*. Infomax performs similarly as RAMICA but FastICA and JADE achieve slightly better performance with increasing *Q*. Such difference could be due to the trade-off between the benefits of having more samples QT and the detriments of more dependent samples. The detriments dominate for Infomax but the benefits dominate for JADE and FastICA.

Effect of *T*. From Table 5, the performance of all of the methods become better with the increasing of *T*, where the improvement of cRAMICA is the most significant (as shown in the last row in Table 5). The improvements for classical ICA methods are less significant because they have to compensate the detriments of more dependent samples. Though the benefits of larger sample size dominate, the detriments of more dependent samples reduce their improvement rate. Comparing the results in Tables 4 and 5, we can also see that *T* has a larger effect on the performance of RAMICA than *Q*.

Effect of σ^2 . In the last study on synthetic BSS, we examine the sensitivity of these ICA methods with respect to noise as shown in Fig. 3(a). We can see that cRAMICA and rRAMICA have similar sensitivity to noise with JADE and FastICA. It may be because they are

all based on the fourth-order cumulants. Infomax is the least sensitive to noise but it performs the worst in most cases. In addition, cRAMICA largely outperforms the others in this experiment.

6.2. Blind image separation

We further perform evaluations on real-world image data. Natural image data tend to have structures in both row and column. Thus, both rRAMICA and cRAMICA should work to some extent. Which one performs better will depend on whether row or column structure dominates. Next, we conduct real data experiments to verify this.

6.2.1. Data

Source images are taken from the Caltech256 repository [38]. We selected 4,424 images with strong higher-order statistics from the total 30,607 images for blind image separation experiments. All selected images are resized to a standard size of 256×256 with 256 gray levels so Q = T = 256.

6.2.2. Experimental settings

We repeat the following process 100 times:

- Randomly select four source images (P = 4).
- Mix them using a mixing matrix randomly generated in the same way as in the synthetic study to produce four mixture images according to (9) (equivalent to the classical ICA model (3)).
- · Recover the sources from the four mixtures by ICA methods.
- Compute the Amari errors accordingly.

In addition, we add noise to the mixing process to do sensitivity study. The average Amari errors are reported.

6.2.3. Image separation results

Fig. 4 presents an example of blind image separation. For illustration, we show the four randomly selected source images in Fig. 4(a) and their mixtures in Fig. 4(b) for which the mixing matrix is generated randomly according to Eq. (9) and they do not suffer from data noise. We also show the performance of FastICA, JADE, Infomax, cRAMICA and rRAMICA in Fig. 4(c)–(g), respectively. From the results, we can see that cRAMICA has achieved the best separation with the best (smallest) Amari error. FastICA and JADE also separated the source images well, while Infomax has the worst separation with the largest Amari error.

Next, we study the performance of blind image separation in a more systematic way. Fig. 3(b) shows the recovery performance across different noise levels. The results of Infomax are above the chosen upper limit in the figure (for clarity) so they are not visible there. We can see that both rRAMICA and cRAMICA can obtain better BSS performance than the other methods when the noise level is below 0.1. This confirms that real-world images contain both row and column structures and both rRAMICA and cRAMICA have their merits. Furthermore, cRAMICA outperforms the other methods by a *large margin* in the *noise-free* case. And this margin reduces as the noise level increases. The observation that cRAMICA outperforms rRAMICA indicates that the column structure is stronger than the row structure on the whole for the selected Caltech256 images.

In addition, we also study and report the Signal to Interferenceplus-Noise Ratio (SINR) loss to measure the performance of real image BSS in the noisy scenario [39]. The mean SINR loss of each ICA method across 100 repetitions is reported in Table 6, and a smaller value means better performance. Both cRAMICA and rRAM-ICA can obtain better SINR than other methods at different noise levels, being consistent with the performance comparison in terms of the Amari error.

(c) Separation by FastICA with Amari error 7.7

(d) Separation by JADE with Amari error 7.2

(e) Separation by Infomax with Amari error 22.9

(f) By cRAMICA with Amari error 6.9

(g) By rRAMICA with Amari error 8.1

Fig. 4. Examples of source images, mixture images and recovered images by ICA methods for the blind image separation problem.

Table 6

Performance of real image BSS in terms of the SINR loss metric. Each value is the average SINR losses over 100 repetitions. The best performed values are highlighted in bold.

Noise Level	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09	0.1	0.15	0.2
FastICA	81.35	34.78	20.77	14.27	10.62	8.25	6.73	5.61	4.80	4.19	2.41	1.71
JADE	78.73	33.23	19.65	13.41	9.94	7.76	6.29	5.25	4.47	3.87	2.24	1.53
Infomax	109.58	53.11	34.39	25.09	19.55	15.88	13.28	11.34	9.84	8.66	5.17	3.51
cRAMICA	73.24	30.45	17.85	12.12	8.94	6.96	5.63	4.69	3.99	3.45	1.99	1.37
rRAMICA	75.20	31.40	18.48	12.58	9.30	7.25	5.87	4.89	4.16	3.60	2.08	1.43

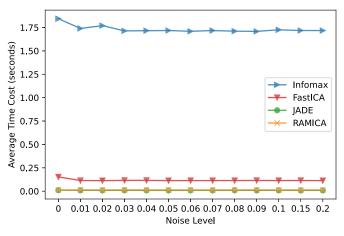

Fig. 5. Average running time comparison on the blind image separation task.

6.2.4. Computational efficiency

Finally, we compare the computational efficiency on this blind image separation task. Fig. 5 shows the average running time of the four ICA algorithms averaged over 100 runs (using MATLAB R2021b on Ubuntu 18.04). With its efficient implementation, JADE is the fastest with an average running time of 0.01s. RAMICA is only slightly slower with an average running time of 0.015s. In contrast, FastICA and Infomax have an average running time of 0.117s and 1.73s, respectively.

7. Conclusion

This paper proposed a new ICA method RAMICA for BSS with data tensor input. It differs from the classical vectorization-based approach and more recent mode-wise approach by dealing with data tensor directly, without vectorization or unfolding. Thus, it can do more general BSS while preserving structural information. We build RAMICA based on random matrix modeling with two versions: row-wise and column-wise. By defining new statistics of random matrix, we develop a two-step RAMICA algorithm with a new cumulant operator and the Jacobi method. Experimental results on both synthetic and real image BSS showed that RAMICA outperformed competing ICA methods greatly in BSS on data tensor, with its two versions having their respective merits. Future directions include extensions of the proposed approach to faster, more robust algorithms, and random-matrix-based machine learning and tensor analysis.

Declaration of Competing Interest
