35 **ABSTRACT**

36

37 Face perception is critical to social interactions, yet people vary in how easily they can recognise their
38 friends, verify an identification document, or notice someone’s smile. There are widespread
39 differences in people’s abilities to recognise faces and research has particularly focused on
40 exceptionally good or poor recognition performance. In this Review, we synthesise literature on
41 individual differences in face processing across different tasks including identification and estimates
42 of emotional state and social attributes. The individual differences approach has considerable
43 untapped potential for theoretical progress in understanding the perceptual and cognitive organisation
44 of face processing. This approach also has practical consequences — for example, in determining who
45 is best suited to check passports. We also discuss the underlying structural and anatomical predictors
46 of face perception ability. Furthermore, we highlight problems of measurement that pose challenges
47 for the effective study of individual differences. Finally, we note that research in individual
48 differences rarely addresses perception of familiar faces. Despite people’s everyday experience of
49 being ‘good’ or ‘bad’ with faces, a theory of how people recognise their friends remains elusive.

68 [H1] Introduction

69 Faces provide many types of information. Using faces, people can recognise others they know and also
70 quite accurately estimate the age, gender or health of strangers and friends. Faces can also be used to
71 judge transient states, for example someone's mood, focus of attention, or speech patterns. The multiple
72 sources of information available in a face are critical for social behaviour, enabling people to identify
73 someone as family, friend or colleague, and to decide whether they should speak to, hug, or stay away
74 from them. These decisions are made quickly and easily, often without reflection. However, these
75 remarkable abilities in face processing are not distributed equally across people.

76 Widespread differences in face perception between individuals have become an important research
77 focus for three reasons. First, everyday experience suggests that some people are better at face
78 perception than others, and some people have strong beliefs about whether they are 'good with faces'.
79 Second, given the wide variety of information available in a face, much theoretical work focuses on
80 whether the processes underlying different perceptual decisions are independent¹. Individual
81 differences techniques are well-suited to addressing these questions in both face processing^{2,3}, and other
82 areas of cognition research^{4,5}. Third, face processing research has a good track record of using
83 converging evidence to build theory⁶⁻⁸. Individual differences methodology can be recruited alongside
84 evidence from experimental psychology, neuroscience, neuropsychology and computational modelling
85 to make significant progress in the field.

86 Research on individual differences in face processing has tended to focus on identity processing.
87 Tests have been designed that measure performance on a relatively small, narrowly defined set of tasks,
88 which often do not capture the richness of daily life. Nevertheless, differences in performance reveal a
89 multidimensional face processing system and its links to broader perceptual and cognitive processes.

90 In this Review, we explore why some people are better at certain face tasks than others, and whether
91 this variation helps to uncover the fundamental processes involved. We summarise the approaches to
92 measuring individual differences and the instruments developed across the broad range of face
93 perception tasks. We then consider the notion of 'holistic' processing — the tendency for faces to be
94 perceived as unitary objects rather than as a collection of parts⁹ — and describe how studies of
95 individual differences inform the representational codes supporting face perception. We highlight the
96 differences between perceiving familiar and unfamiliar faces, and point out the relative dearth of
97 individual differences studies of familiar face processing. Finally, we review the practical issues that
98 emerge for face processing in professional settings. Overall, we provide a snapshot of an approach that
99 contributes to our understanding of face perception and offers opportunities for insights that
100 complement converging evidence in the field.

101 Throughout the Review, we use the term ‘face recognition’ to denote the process by which someone
102 is identified from their face. Recognition of identity is just one component of ‘face perception’, a term
103 that covers face processing for multiple purposes, including decisions about somebody’s expression,
104 age, or attractiveness, as well as their identity. We use the term ‘face processing’ to refer to any of the
105 perceptual, cognitive or neural processes underpinning face perception for any purpose. Finally, person
106 perception refers to the processing of perceptual information across a whole person including, for
107 example, someone’s voice or gait.
108

109 **[H1] Converging research on face perception**

110 Whereas the majority of individual differences research focuses on face recognition¹⁰, there is also
111 individual variation in other aspects of face perception^{11,12}. Knowing how these different abilities co-
112 vary in the population can help reveal the structural and processing constraints that shape the face
113 processing system.

114 The traditional research emphasis in face perception has been on performance in clinical populations
115 or group-level analysis of average measures, in particular to detect transient changes induced by
116 experimental manipulation. By contrast, a focus on the natural variation between people’s face
117 processing abilities represents a fundamental shift in research focus. Although individual differences
118 research presents challenges for measuring natural variation, it also adds novel tools. As in other areas
119 of psychology, a single face perception study rarely fully resolves an issue through a conclusive
120 experiment or simulation. Instead, converging evidence is highly valued, and this is the spirit in which
121 individual differences techniques are becoming popular. Here we describe three major approaches taken
122 by individual differences researchers.
123

124 **[H3] Extreme abilities**

125 Much of the individual differences research literature derives from the observation that there are some
126 individuals who are unusually poor or unusually good at face recognition tasks. In addition to acquired
127 prosopagnosia (the inability to recognise faces as a result of brain damage), there are also people who
128 show poor recognition ability throughout life in the absence of known organic cause, a condition known
129 as developmental prosopagnosia^{13–15} (or sometimes ‘congenital prosopagnosia’: see Box 1). These
130 individuals typically report an inability to recognise familiar people on the basis of their face alone,
131 sometimes termed ‘face blindness’. Research on developmental prosopagnosia is complemented by
132 studies on ‘super-recognisers’^{16–18}, individuals with extremely high face recognition ability relative to

133 the average person. These people often report that they can recognise previously seen faces in
134 challenging conditions, for example in poor lighting, and despite not having encountered them for many
135 years.

136 Recruiting participant groups with extreme abilities enables group-level comparisons between these
137 extreme profiles and average performers. This approach differs substantially from traditional
138 neuropsychological case studies in which an individual is compared to a single control individual or a
139 control group. Group studies on participants selected from extremes of the ability spectrum can offer
140 high statistical power for detecting differences and have the potential to provide insight into the
141 fundamental nature of that ability. This approach can be used to establish dissociations between
142 different subtypes of face processing ability¹⁹, or between face processing and other types of ability.
143 However, the increased power gained by group comparisons relies on a degree of homogeneity within
144 groups and people with developmental prosopagnosia can sometimes display rather diverse symptoms.

145

146 **[H3] Variation within the normal range**

147 There is growing awareness of the value of individual differences research across the entire range of
148 face processing abilities. Whereas face perception variability is sometimes studied to identify target
149 groups (for example, to establish a range of abilities from which one might select people to perform
150 face-related tasks such as checking passports) it is more commonly used to establish associations or
151 independence between variables of interest. The main tool for establishing the relationship between two
152 tasks is correlation – deriving a quantitative measure of the association between performance on two or
153 more different tasks. This method raises issues of the reliability and validity of particular scales of test
154 processing. The composition of the tests themselves is critical to scientific progress.

155 Associations between tests of face perception and other performance measures provide an
156 opportunity to understand the relationships between fundamental processes that are not easily
157 uncovered using traditional group-level analysis. For example, if people who are good at face
158 recognition also turn out to be good at voice recognition, that would provide evidence for some
159 commonality in the processing required of these tasks. Association studies between face processing and
160 broader cognitive tasks – for example IQ tests – can address the key question of whether individual
161 differences in face processing reflect more domain-general differences in perceptual and cognitive
162 abilities^{20,21}.

163

164 **[H3] Structural Variation**

165 The third major approach to individual differences in face perception is to link quantifiable structural

166 variation – for example in genetic factors or brain physiology – to differences in face perception
167 abilities. A series of twin studies has demonstrated that certain face perception abilities – particularly
168 those related to recognition – are highly heritable²²⁻²⁵. Along with the evidence from extreme
169 performers, the twin data has been taken to support a stable, trait-like ability underpinning performance
170 on some face perception tasks. Interestingly, this heritability is not observed for some other face
171 perception abilities, including those related to social attributions, for example ratings of perceived
172 trustworthiness¹². Patterns of findings in which certain abilities are strongly heritable but others are not
173 are a good example of how individual differences research can be used to constrain models of the face
174 processing network in general. For example, heritable face identity recognition abilities signal a
175 structural basis that is consistent with this being a discrete processing module.

176 In addition to genetic factors, individual differences have also been instructive for understanding the
177 relation between face processing abilities and variations in neural physiology. For example, better face
178 processing abilities have been linked to increased grey matter volume in certain regions²⁶⁻²⁸, as well as
179 to neural activity²⁹⁻³¹ and connectivity between regions of the face processing network³⁰ (Box 2).
180 Relatively small participant group sizes in neurophysiological studies means that some of this evidence
181 is preliminary, but cumulative evidence from studies of individual differences provides a promising
182 approach linking face processing abilities to their neural substrates.

183 Finally, researchers have examined the relationship between face processing and certain pathologies.
184 For example, those with low levels of ability in social communication characteristic of Autism
185 Spectrum Disorder tend to perform poorly on a variety of face perception tasks³² including identity³³
186 and emotion recognition³⁴. People with Autism Spectrum Disorder also show abnormal patterns of
187 attention to faces³², as well as divergence from typical cognitive³⁵ and neurophysiological³⁶ markers of
188 face processing. Whether these are directly linked to reduced social communication abilities in Autism
189 Spectrum Disorder, or to other symptomatic sensory atypicalities, is not clear³⁷. Establishing the
190 complex causal links between face processing and more general communicative abilities therefore
191 remains a challenging task²⁵.

192 Many of the questions addressed in studies of individual differences remain unresolved. But
193 accumulating evidence from the various strands we have outlined in this section demonstrates the
194 power of this approach to bring together research from cognitive psychology, genetics neuroscience
195 and psychopathology. By observing associations between these diverse measures of individual
196 differences, a multidimensional system of related face processing abilities begins to emerge, and its
197 mapping to structural properties can be revealed.

198

199 [H1] Face processing abilities

200 A longstanding issue in philosophy, psychology, and neuroscience is the extent to which individual
201 differences in performance on cognitive tasks have a common underlying driver, for example IQ.
202 Alternative ‘modular’ accounts hold that certain encapsulated processes such as early visual processing
203 operate relatively independently³⁸. Face perception provides an important example of modularity in
204 higher-level processing, with converging evidence pointing to a degree of encapsulation: Individual
205 differences in face recognition tasks are independent of general intelligence³⁹ and to some extent
206 general visual processing^{22,40-43}. These findings from the individual differences literature concur with
207 long-established evidence from other research traditions including neuropsychology⁴⁴, neuroscience⁴⁵
208 and behavioural group studies⁴⁶ showing dissociations between face perception and other types of
209 visual processing.

210 In the field of face perception the modularity issue arises in an often polarised debate about the
211 functional specialisation of face processing relative to other high-level visual processing tasks⁴⁶⁻⁴⁸. In
212 fact, individual difference studies show a moderate, rather than sharp, dissociation between face and
213 visual object perception tasks^{20,40}. Some studies report significant associations between face and
214 general object perception ability (r ranging from .00 to .37)^{20,40,42,49,50} whereas face recognition⁴² and
215 perception²¹ do not correlate with non-visual aspects of intelligence. However, associations between
216 face and object recognition are consistently weaker than those between different face (r ranging from
217 .20 to .65)^{20,22,50-54}, or object recognition tasks (r ranging from .27 to .68)^{42,49}. This pattern is consistent
218 with the observations that two thirds of people with developmental prosopagnosia have impaired object
219 recognition abilities⁴³ abilities³⁹ and super-recognisers outperform control groups on non-face object
220 processing tasks¹⁶. Overall, these patterns of associations are not consistent with a strictly modular face
221 processing system, suggesting a graded rather than absolute distinction between face and object
222 perception abilities.

223

224 [H3] Measuring face processing

225 There is a range of face processing tasks used to study individual differences, including recognition of
226 identity, facial expression, and inferences about personal characteristics (Table 1). Tasks measuring
227 recognition of identity are highly over-represented compared to other aspects of face perception.
228 Diverse task formats have been used to study aspects of face processing (Fig. 1). Probing a particular
229 ability with a range of tests is valuable to gain converging evidence. High levels of convergence
230 suggest an underlying common ability, in contrast to highly task-specific abilities. But diversity in task
231 format can also pose problems for inferences about the relatedness between abilities – lack of

232 association could be attributed to differences in superficial aspects of the tasks rather than the
233 underlying abilities.

234 Three key psychometric properties constrain the individual differences approach. First, test-retest
235 reliability, which is the correlation between test scores on the same test across two separate test
236 sessions. This property is critical for interpretation because it places an upper bound on the associations
237 between tests – associations between tests cannot exceed associations between a test and itself.
238 However, estimates of test-retest reliability are not available for most tests. The second property,
239 convergent validity, is the correlation between different tasks that ostensibly measure the same thing.
240 This property is similarly critical⁴² because it establishes that the common variance in test scores is
241 attributable to an underlying ability recruited by the tests, rather than due to artifacts of any particular
242 test – for example the specific images that were used to create it. Third, external validity relates to
243 whether the tests measure what they are intended to measure, by correlating test scores with
244 performance outside the laboratory. In the context of face processing, externally valid tests capture
245 abilities as they are used in daily life, rather than reflecting the highly-specific context of psychological
246 assessment. Thus, whereas test-retest reliability can be measured using a single test (Table 1),
247 convergent and external validity are contingent on comparison with other tests.

248

249 [H3] Facial identity

250 The most common tests of face recognition require participants to remember previously seen faces (for
251 example, ‘which of these faces did you see earlier?’) or to match faces (for example, ‘do these two
252 photos show the same person?’). The results of facial identity processing tests show a wide diversity in
253 abilities across people^{55–57} but an individual’s score is highly stable over time, with test-retest
254 correlations typically above .7 (Table 1)^{22,51,58}. Face recognition is heritable^{22–24}, with correlations of
255 0.7 between scores of monozygotic twins, compared to 0.29 for dizygotic twins²², and estimates of
256 heritability ranging from 68 to 97%^{22,24}. Thus, identity processing can be measured reliably and
257 apparently taps a stable underlying dimension. Yet this evidence is based predominantly on a single test
258 of unfamiliar face memory, the Cambridge Face Memory Test, CFMT⁵⁵. It is therefore important to
259 confirm that this trait generalises beyond a specific test.

260 Regarding convergent validity of face identification tests, associations persist despite substantial
261 changes in task format. Similar results are observed despite differences in memory demands^{20,56},
262 retention interval⁵⁹, and types of response (for example, naming or multiple choice⁴²). The term f –
263 measured by associations between face tasks – is defined as a general factor underlying face identity
264 processing ability²¹. The reported correlation between tests of face memory and matching is typically in

265 the range of .5 to .7^{21,51}. It has been estimated that f can account for up to 25% of the variance across
266 face recognition tests – including the popular CFMT, Before They Were Famous Test (BFTWF), and
267 Glasgow Face Matching Test (GFMT)²⁰ – and it has been linked to particular polymorphisms from a
268 genome-wide association study^{55,60}. Whereas these face tasks tend to correlate, reports typically show no
269 reliable associations between performance on these tasks and visual processing tasks for other objects.
270 This pattern is consistent with research in object recognition reporting a general factor accounting for
271 shared variance in novel object processing tasks (denoted o ⁴⁹). The general object factor shows
272 relatively weak association with the CFMT ($r = 0.28$), providing converging evidence that face identity
273 processing is somewhat isolated from more general object processing ability.

274 Another key question is whether face recognition is a unitary ability across familiar and unfamiliar
275 faces. The study of identification commonly focuses on unfamiliar faces, despite the fact that
276 recognition of familiar people is an important component of daily life (only 3 out of 17 face recognition
277 tests use familiar faces, Table 1). This under-representation may be due to recognition of familiar faces
278 being generally easier than recognizing unfamiliar faces, so it is challenging to design discriminating
279 tasks. Furthermore, there is no common set of faces that are familiar to all individuals. People are
280 highly bound to their cultures, age and social groups, each having distinct sets of familiar faces such as
281 celebrities, politicians, and famous athletes⁶¹. There are large behavioural differences between the
282 perception of familiar and unfamiliar faces, which have been argued to reflect qualitatively different
283 processing^{62–64}. Some authors have reported an absence of correlation between familiar and unfamiliar
284 face recognition using matching tasks⁶⁵ but these tests tend to give near-perfect results for familiar
285 faces, limiting the measurement of their association. Studies using tests of familiar face naming tend to
286 find significant associations between familiar and unfamiliar face recognition^{20,42,66}, consistent with the
287 idea that face identity processing is a relatively coherent ability.

288 Self-report measures of face recognition ability correlate very highly with each other ($r = .82$)⁶⁷, but
289 tend to predict test performance less well (r ranging from .14 to .52)^{68–72}. Ad-hoc (non-psychometric)
290 tests of people's insights into their face recognition abilities have reported even smaller associations to
291 actual performance ($r = .13$ to .26)⁷¹. This modest relationship between self-report and face identity
292 tests could be due to a general lack of metacognitive insight⁷³. Another possibility is that tests of face
293 recognition do not capture the processes involved in everyday recognition. This might also explain
294 relatively low correlations between standardised tests and more naturalistic learning and recognition
295 tasks, for example between CFMT scores and viewers' recognition of faces from the TV show Game of
296 Thrones ($r = 0.45$)^{74,75}. Thus, although face identity processing tests show good internal, convergent,
297 and divergent validity, important questions remain regarding their external validity. Establishing

298 external validity is critical if face identity tests are to be used for selecting good face recognisers in
299 professional settings¹⁸, and so we return to this issue later (see Practical Implications).

300

301 **[H3] Expressions and impressions**

302 The study of emotion perception in faces has been dominated by a debate about whether a few ‘basic’
303 emotions are expressed and perceived similarly by all humans^{76–78}. However, using the individual
304 differences approach, some studies of subtle variations in expression recognition show reliable
305 between-person differences in the ability to judge emotion^{11,79–81}. In contrast to identity processing, the
306 pattern of correlation on tests of emotion recognition is highly sensitive to changes in the particular
307 emotions being expressed² and the task format¹¹. This pattern points to a lack of convergence onto a
308 unitary process for the visual analysis of facial expression. Instead, it seems that the recognition of
309 different emotions (for example, happiness or fear) call on somewhat different abilities^{2,3,82}.

310 One focus of individual differences research has been social and aesthetic judgments made to
311 unfamiliar faces (that is, the faces of people unknown to the viewers). When asked to judge the
312 trustworthiness or dominance of a face, viewers tend to agree with each other, even though these
313 judgements are typically not accurate indicators of a person’s true character^{83–86}. People asked to judge
314 the attractiveness of a face, show moderate levels of agreement, albeit lower than their ratings of
315 trustworthiness/dominance^{87–89}. Despite some agreements between people in making social judgments,
316 there remains some variation, pointing to idiosyncrasies in individual perceptions, which appear to be
317 relatively stable over time^{12,89}.

318 Unlike face identity processing, variation in social judgements is not associated with genotype. A
319 large-scale twin study showed that trustworthiness judgements of unfamiliar faces vary more strongly
320 with the viewers’ personal experiences than their genetics¹². Individual variation in aesthetic
321 judgements of attractiveness is also associated more strongly with environment than genes⁸⁹. The
322 implication of current research is that social judgements are a product of social learning^{78,84,90}, and
323 researchers are beginning to propose mechanistic accounts of this learning at an individual level. For
324 example, trustworthiness and attractiveness judgments appear to be linked to transitory changes such as
325 smiling or warm expressions^{91–93}. This observation reflects an emerging view that social signals from
326 faces are intertwined in real world tasks, limiting the external validity of many lab-based tasks that use
327 artificial faces or highly standardised images^{94–96}.

328

329 **[H3] Multimodal person perception**

330 In daily life, people perceive information about each other using multiple sources, including cues from
331 voices, bodies, clothing, and context. Lab-based experiments using isolated faces can obscure the fact
332 that recognising or making a perceptual judgement about someone usually involves many cues
333 presented together and often in redundant combinations. For example, a viewer might recognise a
334 friend from their face, their walking style, a particular jacket, and the fact that they arrive at an arranged
335 meeting on time (Fig. 2). Variation in real life person perception might incorporate differences in all
336 these dimensions too – each requires cognitive and perceptual decisions, and so they may be subject to
337 individual variation between people.

338 Within the visual domain, the ability to recognise facial identity is only weakly correlated with the
339 ability to process cues from bodies and movement⁹⁷, suggesting somewhat separable processes. Beyond
340 vision, there are widespread differences in people’s ability to recognise voices⁹⁸⁻¹⁰⁰ over and above
341 general differences in auditory perception¹⁰¹. On tests of identity using matching and similarity tasks,
342 there is some evidence for an association between recognising faces and recognising voices¹⁰² and
343 some individuals have high ability levels in both¹⁰³. Associations are typically quite small (r ranging
344 from .24 to .41)¹⁰² and so cross-modal mechanisms do not seem to underpin all voice recognition. The
345 relatively weak association between face and voice recognition is further supported by the report of
346 individuals with developmental prosopagnosia but intact familiar voice recognition¹⁰⁴.

347 There are also associations between decisions about attractiveness from voices and faces (r from .15
348 to .34)^{105,106}. The perception of attractiveness appears to be multimodal and can be influenced by
349 olfactory cues¹⁰⁷. Well-established individual differences in olfactory sensory apparatus¹⁰⁸ and effects
350 of scent on other impression judgments¹⁰⁷ highlight the potential for individual differences in the
351 associations between olfactory and visual cues to social judgments.

352 Individual differences in judgements of emotion from faces and voices also appear to show common
353 processing across modalities^{3,11} and this association extends to tactile perception, elicited by the touch
354 of another person¹⁰⁹. Connolly and colleagues^{2,3} identify shared variability for tests of expression
355 recognition accuracy from both face and voice stimuli, which they describe as a ‘supra-modal’ factor
356 underlying emotion perception. This factor is related to the ability to introspect on one’s own emotional
357 state, which varies dimensionally in the typical population³. The association between face processing
358 and social abilities in the general population has implications for the diagnosis of pathology (Box 1),
359 for example emotion processing impairments in psychopathy^{110,111} and autism¹¹².

360 Studying individual differences in face processing abilities has contributed to a greater
361 understanding of the subtle ways in which the different aspects of face processing are related.
362 Associations between performance on multiple face tasks, including identity recognition and

363 expression perception, points to some shared underlying processes. For emotion perception
364 particularly, these processes appear to be multi-modal, incorporating vision, audition and touch.
365 However, it has also been possible to establish some key differences between different face processing
366 abilities, for example the strong genetic component underlying identity recognition, but not social
367 judgements.

368

369 **[H1] Underlying representations**

370 Research on the associations between different abilities, as described in the previous section, is
371 complemented by a parallel focus on the cognitive mechanisms. Models of face perception posit
372 multiple (serial or parallel) processing stages between visual input and perceptual decisions⁶. Neural
373 models instantiate these networks in connected brain regions⁷ (Box 2). In the study of individual
374 differences, these networks are revealed as systems of related abilities that provide converging sources
375 of information to support perception. Individual differences research tends to report some overlap in
376 people's abilities in recognition and emotion perception^{2,3,11,113-115}. This pattern suggests some shared
377 representational resource between abilities to recognise identities and emotions.

378 Patterns of association and dissociation help clarify the modular structure and representations of the
379 face processing system. For example, research on developmental prosopagnosia has found that some
380 individuals show impaired gender discrimination¹¹⁶ but spared facial age estimation^{19,117}. This pattern
381 provides good evidence that perception of age is not dependent on identity or gender perception.

382 These studies begin from an observed data pattern to determine the underlying cognitive processes.
383 Working in the reverse direction, an understanding of the underlying representations used by the face
384 processing system can help to explain observed differences in performance. We examine this latter
385 approach next.

386

387 **[H3] Holistic processing**

388 Holistic processing refers to the idea that perception of a whole object (or Gestalt) has precedence over
389 perception of its parts. Faces are widely believed to be perceived more holistically than other types of
390 objects⁹. Individual facial features (for example, eyes or noses) are easier to remember when embedded
391 in a face than in isolation¹¹⁸. Similarly, when the top and bottom halves of two different faces are
392 aligned to form a new face, the composed face appears as a new identity¹¹⁹.

393 The importance of holistic face processing has led to the hypothesis that the extent to which
394 different people process faces holistically might underpin differences in their face processing

395 ability^{10,59,120,121}. However, this hypothesis is not well supported among individuals with face
396 processing in the typical range. One of the most popular measures of holistic processing is the
397 Composite Face Effect¹¹⁹, a phenomenon in which the top and bottom halves of two different faces are
398 aligned and tend to fuse perceptually into a single new face. This fusion impedes the separate
399 processing of the face halves compared to when they are not aligned. Some studies show weak-to-
400 moderate correlation between the composite face effect and performance on the CFMT^{59,121,122}, but
401 others have found no association with CFMT^{21,123} or other face recognition tasks^{59,124}. The performance
402 of individuals with developmental prosopagnosia also provides mixed evidence for an association
403 between holistic processing and face recognition ability. Some studies have found slightly poorer
404 holistic processing in individuals with developmental prosopagnosia by comparison to controls^{125–127}
405 while others have found no difference^{124,128–130}.

406 Another challenge to the use of holistic representations as an explanation for differences in face
407 processing is that a person's ability to perform face perception tasks from whole images is highly
408 correlated with their ability to recognise isolated face features¹³¹. Some individuals with developmental
409 prosopagnosia have equivalent impairment on face recognition from isolated features and from whole
410 faces¹⁰⁴, and a hallmark of super-recognisers is their ability to identify faces from relatively limited
411 local face information^{132,133}. Furthermore, recognition is less impacted by distortions that change the
412 spatial layout of facial features in high compared to low performers within the typical range¹³⁴, and
413 those at the top of the typical range are less sensitive to changes in global shape of a face^{135,136}. These
414 findings suggest the need for a more sophisticated understanding of the representational differences
415 underlying face processing ability¹³⁷.

416 Progress in this area also relies on a greater understanding of the tasks themselves. Problems of
417 measurement have dominated research on holistic processing for over a decade^{59,121,138,139} and the
418 challenge of developing valid and reliable measures appears intractable¹³¹. Even the best-established
419 measures of holistic processing suffer from very low reliability and do not correlate with differences in
420 face recognition performance despite best practice in psychometric approach^{131,140,141}. These
421 observations might signal a problem with the construct of holistic processing itself. Other measures of
422 holistic processing, including face inversion effects (faces are harder to process upside down) and part-
423 whole effects (recognition of isolated features is easier when they are embedded in a face) also correlate
424 very poorly with each other¹²⁴. This pattern is perhaps symptomatic of a broader lack of clarity in
425 operationalising processing mechanisms in the field^{137,142}. Substantial methodological and conceptual
426 challenges need to be overcome to understand how differences in underlying representations give rise to
427 differences in ability.

429 [H3] Unfamiliar and familiar faces

430 Research on individual differences has overwhelmingly examined recognition of unfamiliar faces, yet
431 the faces of familiar people comprise much of personal daily experience. Group-level evidence shows
432 that familiarity is directly related to recognition success, viewers are much better at recognizing
433 familiar than unfamiliar faces^{8,143-145} and higher levels of familiarity exert more powerful modulating
434 effects on neural responses^{64,146-150}. If differences between familiar face representations are important
435 for performance within an individual, these differences could also be important between individuals.

436 Performance in recognising famous faces is moderately related to performance on an unfamiliar face
437 test (CFMT), with correlations ranging from .55⁴² to .33²⁰. There is also some evidence that the
438 representations underlying familiar and unfamiliar face recognition tasks are distinct. Whereas high
439 performers on a famous face test were less reliant on global face shape than low performers, high
440 performers on the CFMT (unfamiliar faces) showed the opposite pattern and were more reliant on
441 global face shape¹³⁶.

442 For familiar faces, idiosyncratic cues contribute to the representation of identity^{151,152}. One face
443 might be recognised from a characteristic smirk, another from distinctive facial speech movements.
444 Analyses of multiple images of the same person reveal not only consistent differences between people,
445 but also idiosyncratic within-person variability^{153,154}. To become familiar with a new face, one needs to
446 experience the range over which that face can vary^{155,156}. This multidimensional view of familiar face
447 representations has implications for individual differences in responses to unfamiliar faces too. People
448 who are particularly skilled at unfamiliar face recognition recruit elaborate semantic and emotional
449 representations more commonly used for familiar face processing^{29,30}. In this way, the difficulty of
450 unfamiliar face recognition may be alleviated to some extent in skilled viewers.

451 Representations of the same faces, both familiar and unfamiliar, also diverge considerably across
452 individuals. For example, participants disagree entirely which images of unfamiliar faces look most
453 similar to one another¹⁵⁷, and there are large differences in the photos that people report as showing the
454 best likeness of a familiar face¹⁵⁸. Research on the representations underlying these differences is rare
455 and it remains puzzling why different viewers show different patterns of similarity between the same
456 familiar faces.

457 In summary, researchers have sought to explain differences in performance on face tasks through
458 differences in viewers' underlying representations. The degree to which people tend to use holistic
459 processing was once thought to be a good candidate to explain variation in face recognition
460 performance, but the evidence is weak. Differences between recognition of familiar and unfamiliar face

461 recognition offer some promise for understanding the relationship between people’s representations and
462 their performance. Further exploration of this relationship will require detailed investigation of people’s
463 idiosyncratic representations of the faces they know.

464

465 **[H1] Practical implications**

466 In addition to providing theoretical understanding, studying individual differences brings practical
467 implications. For example, face perception in disorders influencing social cognition has clinical
468 relevance (Box 1) and social consequences for individuals with these disorders¹⁵⁹⁻¹⁶². There are also
469 clear societal implications of individual differences in face recognition. The outcomes of face
470 identification decisions in security and forensic settings can often be profound – impacting civil
471 liberties and even leading to wrongful convictions – and the science of individual differences can help
472 address these problems.

473

474 **Identity-checking**

475 Tasks that involve checking the identity of unfamiliar people are known to be difficult and error-prone.
476 Error rates of 20-30 percent are common in studies asking viewers to match two different photos of the
477 same person, taken on different occasions, even when using high quality images taken in good
478 lighting¹⁶³. This difficulty extends to professionals who conduct daily face matching, such as in
479 passport control or forensic face identification. In a meta-analysis of 29 comparisons between
480 professional groups and participants from the general population on tests of unfamiliar face identity
481 matching, 40% of tests showed equivalent face matching accuracy in these groups¹⁶⁴. High error rates
482 were found in staff performing a variety of important identity verification roles in border control¹⁶⁵,
483 government offices¹⁶⁶, passport issuance^{167,168}, police departments¹⁶⁹, security firms¹⁷⁰ and banks¹⁷¹.
484 Simply performing identification tasks in daily work is not sufficient for expertise. Furthermore, current
485 approaches to training in many professional settings are ineffective (Box 3).

486 The discovery of reliable individual differences in face recognition provides one means of
487 addressing this problem. It is becoming increasingly popular to select people for specialist face
488 identification roles on the basis of their natural ability as measured by standard tests. This strategy has
489 been used by the London Metropolitan Police^{172,173} and the Australian Passport Office¹⁶⁸, with groups
490 selected for high face performance showing 10-20% gains in accuracy over control groups.

491

492 **Forensic face identification**

493 Facial forensic examiners – who analyse similarities and differences between face images to provide
494 evidentiary reports for police investigations and criminal trials – outperform standard participant groups
495 by roughly the same margin^{57,164,174,175} as selectively-recruited, but untrained, super-recognisers. In
496 contrast to super-recognisers’ quick and intuitive recognition ability, forensic abilities are founded on
497 years of deliberate training in comparing images of unfamiliar faces¹⁷⁶ and involve slow, analytic
498 comparison^{174,175}.

499 Forensic identifications are also made by eye-witnesses. These are highly vulnerable to error, with
500 meta-analysis suggesting that 50% of eyewitness lineup selections are wrong¹⁷⁷. Given the range of
501 face recognition abilities in the general population, it is likely that a large proportion of errors are made
502 by people with relatively poor face recognition abilities. Researchers have examined the use of tests of
503 face identification to screen eyewitnesses, an approach that pre-dates broader interest in individual
504 differences¹⁷⁸. Face recognition tests can be used to predict eyewitness errors¹⁷⁹, by allowing law-
505 enforcement officers to weigh witnesses’ identifications against their objective abilities. Furthermore,
506 eyewitnesses are often overconfident, and tests can establish whether particular individuals tend to
507 over-estimate their recognition performance, providing a level of credibility to testimony^{73,180,181}.

508 The potential for individual difference research to improve accuracy in real-world tasks relies on
509 reliable and valid tests. From an applied perspective, valid tests must correspond with real-world tasks.
510 As a basic example, a face memory test might not be an optimal measure for professionals who are
511 required to match but not remember faces. However, there is sufficient task diversity among relevant
512 practitioners to present a nontrivial challenge in choosing tests for specific professional contexts¹⁸.
513 Forensic identifications made from CCTV involve a complex set of cognitive demands¹⁸² and might
514 incorporate cues beyond the face including behaviour, gait, or clothing. The use of these cues these
515 might each represent separate skills⁹⁷. Preliminary evidence suggests that face recognition tests are not
516 especially reliable predictors of performance on CCTV monitoring tasks^{75,183} indicating that basic
517 understanding of skills underpinning accuracy on different real-world identification tasks is lacking.

518 The challenges in forensic face identification echo the lack of diversity in measures for effectively
519 capturing everyday abilities. Batteries of face tests that target distinct subskills provide an alternative to
520 reducing ability to a single test score^{18,52}, and might provide the necessary flexibility to capture the
521 multidimensional nature of person identification for both applied and theoretical use.

522

523 **Human-AI collaboration**

524 Face recognition in applied settings increasingly relies on combined processing by humans and
525 technology. Deep neural network approaches to facial recognition have been highly successful and the

526 best-performing systems are now as accurate as both super-recognisers and facial forensic examiners⁵⁷.
527 Such automated processes are used for passport control in some countries as well as police searches for
528 suspects in image surveillance¹⁸⁴. Critically, in many of these applications, the technology does not
529 replace human processing but rather presents operators with arrays of potential matches for follow-up.
530 This procedure automatically makes easy match decisions, leaving more difficult matches to human
531 reviewers and error rates in human review can be as high as 50%¹⁶⁸. Thus, this type of forensic
532 identification can be problematic in the same way as traditional identification processes, such as
533 eyewitness lineups¹⁷⁷.

534 Selecting people with the necessary skills to review matches generated by facial recognition
535 technology is a potential way to reduce error rates. Moreover, it appears that personnel selection can be
536 tailored to the specific face recognition algorithms that are being used. Statistical aggregation of the
537 decisions made by algorithm and high performing humans produces accuracy that exceeds either
538 algorithms or humans alone⁵⁷. This statistical combination benefit is driven by independent processes
539 recruited by algorithms and human perceivers. Given the present revival of interest in deep learning
540 networks as models of face processing^{185,186}, evaluating similarities and differences between human and
541 machine processing can also lead to theoretical advances.

542

543 **[H1] Summary and future directions**

544 Individual differences research is a complementary approach to traditional group studies for
545 understanding face perception. In a field that has traditionally drawn on converging evidence,
546 individual differences research enables new questions to be asked and can address some long-standing
547 issues. Although there has been considerable research focusing on people with extreme levels of ability
548 (individuals with developmental prosopagnosia and super-recognisers), there is considerable potential
549 for broader scientific progress across the full scale of abilities.

550 The study of individual differences has also highlighted some major problems in the field of face
551 perception. Perhaps the most significant of these is the problem of measurement. The construction of
552 reliable and valid tests lies at the heart of an individual differences research programme, but tests of
553 face perception remain comparatively weak in these properties. Without reliable tests, it is impossible
554 to draw valid conclusions. Although the construction of new tests remains a challenge, it would be
555 relatively straightforward for researchers to only use tests with published test-reliability measures. The
556 problem of reliability in psychological measures is not specific to the study of face processing, but the
557 problem seems particularly acute in this field because there are multiple tests for measuring each aspect
558 of face processing (Table 1).

559 The issue of measurement has also highlighted another problem with the theory-led approach to
560 some face recognition questions. A good example is the widespread view that holistic perceptual
561 processing underlies face perception. However, the set of tests used to measure holistic processing
562 correlate very poorly with each other¹²⁴ - a key finding that has perhaps not yet had the influence it
563 deserves. Theoretical statements based on holistic processing are common and the field has perhaps
564 been too willing to adopt these generalisations without clear operationalisation¹⁴². At the very least,
565 holistic processing accounts of face perception should specify the relevant measure of holistic
566 processing¹³¹.

567 Another major challenge remains in eliciting general principles of face perception while
568 acknowledging that every person has different experience with faces. Developing methods for studying
569 variation in familiar face recognition will be a major challenge, given the highly idiosyncratic set of
570 personally familiar faces and the laborious processes required to tailor experimental materials to
571 individual participants^{64,148,149,187}. For example, one person might not recognise Barack Obama and
572 another might not recognise Kim Kardashian – discrepancies that often lead to mutual disbelief.
573 Approaches targeting specific cohorts of TV viewers who have comparable perceptual exposure could
574 offer a promising solution to this methodological problem⁷⁴. Most studies of familiar face perception
575 treat familiarity as a binary categorisation (familiar/unfamiliar), a methodological constraint which has,
576 to some extent, obscured our understanding using traditional experimental approaches¹⁵⁴. It remains to
577 be seen whether individual differences approaches, which conceptually differentiate between people,
578 can be harnessed to capture natural idiosyncrasy.

579 In this Review, we have emphasised the implications of multiple sources of information for face
580 perception. We have shown how individual differences approaches shed light on the perceptual
581 architecture necessary to use faces in the flexible ways that humans do. Yet, the biggest unsolved
582 problem in face perception remains how someone recognises the people they know.

Table 1. Tasks used to measure individual differences in face processing abilities. Only tasks that were specifically developed to test individual differences in face processing are included, where normative accuracy data is available based on non-clinical adult samples of more than 80 participants. Test-retest reliability is presented, and ranges indicate variable reliability in sub-measures reported. This table signals a maturing field of individual differences in face processing with progress in testing a range of face processing abilities, albeit most heavily concentrated in identity processing.

Target ability	Task type	Task	Test-retest reliability
Identity	Perceptual matching	BFRT, Benton Face Recognition Test ^{188, 189}	-
		Glasgow Face Matching Test ⁵⁶	.77 ⁵⁴

1254
1255
1256
1257

1258 **Figure 1. Taxonomy of tasks used to measure face processing abilities.** (A) Perceptual matching
1259 involves deciding whether two or more images match on a given dimension (here: identity). (B)
1260 Perceptual discrimination requires comparing two or more images on a given dimension and either
1261 choosing most/least, or ranking from high to low (here: expression). (C) Recognition memory requires
1262 studying faces and some time later memory for the faces is tested. (D) Naming tasks require naming a
1263 person or labelling an expression, sometimes from a set of predefined labels. (E) Rating tasks ask
1264 participants to rate a single image on a dimension using a Likert scale. (F) Self-report measures ask
1265 participants about their face processing experiences in everyday life. Correlation of tests measuring the
1266 same ability across different task formats establishes convergent validity, but differences in task format
1267 can also interfere with measurement of association between different abilities.
1268

1269 **Figure 2. Everyday decisions depend on rapid decoding of multidimensional facial cues.** Everyday
1270 decisions are made in rich and dynamic environments where multiple cues from multiple senses are
1271 integrated and linked with complex social contexts. Coloured boxes list some of the ambient visual
1272 cues that might influence perceptual judgments on given dimensions in real world tasks. For example, a
1273 decision about where to sit on a bus might be contingent on both identifying your colleague and on
1274 whether her mood would be conducive to casual conversation (is she upset?). Indeed those cues might
1275 not be independent, if for example you have only encountered your colleague in a happy mood then her
1276 expression might influence the identity judgment itself. Situational contexts such as the bus route, and
1277 the clothes worn by the men who might be arguing, are also likely to influence judgments.

1297 **Box 1: Defining developmental prosopagnosia**

1298 Acquired prosopagnosia is characterised by impairment of face processing resulting from brain
1299 damage, but developmental prosopagnosia is not linked to known structural or genetic pathology.
1300 Nevertheless, poor face processing abilities can have severe negative impacts on social interactions^{159–}
1301 ¹⁶². The problem of diagnosis is therefore critical. It is unclear whether developmental prosopagnosia is
1302 better conceptualised as the low-end of the range of typical ability or as a condition in its own right,
1303 independent of typical variability^{204,205}. Understanding the dimensional structure of individual
1304 differences in face processing can help better define developmental prosopagnosia and its association
1305 with other conditions.

1306 No genetic markers have yet been identified for developmental prosopagnosia, and reported neural
1307 abnormalities vary between studies (Box 2). In the absence of reliable markers, the definition of
1308 developmental prosopagnosia is purely based on behavioural performance on tests of face identity
1309 processing or questionnaires probing everyday face recognition. Accurate diagnosis is therefore
1310 conditional on the psychometric properties of these measures.

1311 That some people with developmental prosopagnosia show impaired holistic processing but others
1312 do not might reflect ‘cognitive heterogeneity’ of the condition^{116,206}, which could signal a family of
1313 related subtypes of prosopagnosia rather than a unitary condition²⁰⁷. This proposal would be consistent
1314 with a genetic basis for the condition, despite the current absence of markers: many inherited disorders
1315 are end-points of quantitative dimensional traits determined by multiple genes exerting small effects,
1316 resulting in heterogeneity across a group of individuals^{196,204,208}.

1317 Defining developmental prosopagnosia as a condition is further complicated by age-related declines
1318 in ability^{50,209}, and the need to exclude the contributions of associated conditions. Some of these
1319 conditions do have a clear organic basis (for example, macular degeneration²¹⁰, Alzheimer’s
1320 pathologies²¹¹, frontotemporal dementia^{212,213}) and produce associated progressive deficits in face
1321 perception and memory abilities. The basis of other conditions is less well understood, for example
1322 Autism Spectrum Disorder (ASD)^{32,33,37}, and Schizophrenia²¹⁵. The complexity of these disorders
1323 involve social and perceptual deficits that are not specific to faces²⁵ and manifests as heterogeneity in
1324 the patterns of face processing impairment.

1325 When symptomatic of broader conditions, patterns of impairment reflect the multidimensionality of
1326 face processing abilities. Some disorders are associated with both impaired emotion and identity
1327 processing (Autism³⁴, Schizophrenia²¹⁵, Anxiety⁸²). Other conditions selectively impair expression
1328 recognition (Parkinsons²¹⁶, Psychopathy¹¹⁰). Individual difference studies can improve understanding of
1329 the links between emotion processing deficits⁸² and face abilities in the typical population. Aside from

1330 Parkinson's, these conditions involve traits that vary dimensionally in the typical population^{81,217,218} and
1331 so associated face processing impairments have implications for non-pathological variation^{3,25,219–}
1332 ²²¹.

Box 2: Neural bases of face recognition

Examining anatomical brain differences and their relation to different ability levels can help improve understanding of functional aspects of face processing abilities. Most studies on this topic have focused on differences in blood flow within face-selective regions, measured using functional Magnetic Resonance Imaging (fMRI). Some regions have been functionally defined as ‘face-selective’, and differential activation to faces and non-face objects can then be measured to capture face-selective responses at the individual level²²². Individual differences are found in the precise locations of these regions^{223,224}, and they are mostly stable over time within individuals^{225,226}.

The Fusiform Face Area (FFA) is a functionally defined area that selectively responds to images of faces across repeated brain scans (figure panel a, dark blue). Some studies show correlations between scores on face identification performance and FFA activation strength^{29,30} and region size^{30,227}. However a number of studies report no association^{228–230}. This inconsistency might be due in part to small sample sizes, which are not well suited to individual difference analysis. Some comparisons of FFA activation in people with developmental prosopagnosia to controls show reduced activity^{229,231,232}, but others show no difference²³³. Inconsistency might also arise from poor reliability of brain responses²³⁴. Test-retest reliability of FFA activation has not been examined rigorously, although one study does show relatively high stability in this measure over different presentations of faces in the same experimental session²³⁰.

An association has also been found between FFA grey matter volume and performance in face recognition^{26–28}. A small number of studies using electrophysiological recordings from the scalp (ERPs), have also reported correlations between face-specific components and face recognition performance^{115,235,236}. Despite high reliability of some ERP measures over repeated testing²³⁷, in each of these studies correlations between multiple face-selective ERP components were low ($r = .3$), and the degree to which the components were face-selective did not reliably distinguish developmental prosopagnosia from typical recognition abilities²³⁸.

The FFA is just one part of the neuronal network that has been identified as responding selectively to faces (see figure). But outside the FFA, the association between individual differences in face recognition and brain response in specific regions are relatively inconsistent across studies (light blue and gray in figure: Occipital Face Area, OFA; Anterior Temporal Lobe, ATL; Amygdala, AMG; Superior Temporal Sulcus, STS)^{29,30,239}. The degree of network connectivity, both within this core set of regions and beyond, correlates with measures of face recognition³⁰ and reduced communication between areas has been implicated in developmental prosopagnosia^{239–241}. The importance of interconnection is also supported by structural investigations of white matter connections between

1391 cortical areas (figure panel b, dark blue), with structural deficits of these fibre tracts reported in
1392 developmental prosopagnosia²⁴²⁻²⁴⁴.

1419 **Box 3: Training face recognition**

1420 The extent to which face recognition abilities can be improved with training has implications for
1421 understanding individual differences and plasticity. Face recognition ability does not develop fully until
1422 after the age of 30^{50,209} and people's history of perceptual exposure to faces influences their
1423 abilities^{245,246}. This flexibility in the face processing system could support training, and hence benefit
1424 people with developmental prosopagnosia and those using face recognition professionally.

1425

1426 **[H1] Training impaired face abilities**

1427 Attempts to train face recognition abilities of adults with developmental prosopagnosia have been
1428 largely unsuccessful. One approach has been to train a holistic processing strategy when learning
1429 previously unfamiliar faces, but accuracy benefits from these methods are rarely found. Where they are
1430 reported, the benefits generalise poorly to faces not included in the training, and do not transfer to
1431 superficially different faces, for example photos taken with different cameras or lighting²⁴⁷. This poor
1432 generalisation limits the clinical benefit of training and is consistent with earlier failed attempts to
1433 improve face recognition performance in patients with acquired prosopagnosia^{248,249}.

1434 Another approach is to encourage use of individual face features for identification of familiar faces.
1435 Many people with developmental prosopagnosia report using distinguishing facial features to identify
1436 familiar faces¹⁶². In a case study, researchers were able to teach children with developmental
1437 prosopagnosia to recognise familiar faces by memorising three distinctive features of each person's
1438 face²⁵⁰ and anecdotal evidence suggests that these improvements carried into daily life. Other studies
1439 have also produced promising results training children with developmental prosopagnosia²⁵¹,
1440 suggesting that treatment in early development could confer some benefit. However, training does not
1441 transfer well to more naturalistic task conditions, a finding that is consistent with attempts to train face
1442 recognition in the broader population²⁵².

1443

1444 **[H1] Training typical face abilities**

1445 Training in applied settings tends to be tailored to the specific task of matching unfamiliar faces¹⁷⁶. A
1446 large-scale evaluation of professional training courses showed no learning beyond the specific faces
1447 used in each course¹⁶⁹. In laboratory studies, collaborative face matching decisions with another
1448 person^{253,254}, and accuracy feedback on decisions²⁵⁵ produce small benefits to accuracy. Improvements
1449 were specific to individuals with poorer recognition skills and were small in comparison to individual
1450 differences. A common element might be participants' realization that the task is more difficult than
1451 they expect it to be, leading them to more careful analysis. Some paradigms have successfully

1452 improved accuracy by directing participants' attention to diagnostic features^{175,256}, which would be
1453 consistent with the benefit of additional analysis.

1454 Given the very large benefits of familiarity for face recognition^{62,257}, another approach has been
1455 to develop familiar face representations. Substantial improvements are found when participants view
1456 multiple different photos of the same face^{155,156,258-260}, encouraging the formation of a coherent
1457 representation across variability. However, these benefits do not generalise to new faces^{155,258}, limiting
1458 their value in applied settings.
