Current Biology

Flexible and digestible wood caused by viral-induced alteration of cell wall composition

Highlights

- Apple rubbery wood (ARW) symptoms are caused by decreased lignin in woody tissue
- RNAseq, proteomics, and metabolomics suggest phenylalanine levels decrease
- Virus-activated small interfering RNAs (vasiRNAs) are generated in response to ARWV infection
- VasiRNAs cause siRNA-based downregulation of phenylalanine ammonia

In brief

Apple rubbery wood (ARW) infections cause the branches to become abnormally flexible. Allen et al. demonstrate that the symptoms are caused by a specific decrease in lignin deposition, resulting from decreased flux through phenylalanine ammonia lyase (PAL). PAL is downregulated by siRNAs that are generated by the plant upon ARW infection.

SUMMARY

Woody plant material represents a vast renewable resource that has the potential to produce biofuels and other bio-based products with favorable net CO₂ emissions.^{1,2} Its potential has been demonstrated in a recent study that generated novel structural materials from flexible moldable wood.³ Apple rubbery wood (ARW) disease is the result of a viral infection that causes woody stems to exhibit increased flexibility.⁴ Although ARW disease is associated with the presence of an RNA virus⁵ known as apple rubbery wood virus (ARWV), how the unique symptoms develop is unknown. We demonstrate that the symptoms of ARWV infections arise from reduced lignification within the secondary cell wall of xylem fibers and result in increased wood digestibility. In contrast, the mid-lamellae region and xylem ray cells are largely unaffected by the infection. Gene expression and proteomic data from symptomatic xylem clearly show the downregulation of phenylalanine ammonia lyase (PAL), the enzyme catalyzing the first committed step in the phenylpropanoid pathway leading to lignin biosynthesis. A large increase in soluble phenolics in symptomatic xylem, including the lignin precursor phenylalanine, is also consistent with PAL downregulation. ARWV infection results in the accumulation of many host-derived virus-activated small interfering RNAs (vasiRNAs). PAL-derived vasiRNAs are among the most abundant vasiRNAs in symptomatic xylem and are likely the cause of reduced PAL activity. Apparently, the mechanism used by the virus to alter lignin exhibits similarities to the RNAi strategy used to alter lignin in genetically modified trees to generate comparable improvements in wood properties.^{6–8}

RESULTS AND DISCUSSION

Secondary xylem morphology is perturbed by apple rubbery wood disease

Concerns over the rising carbon footprint and depletion of non-renewable fossil fuels have encouraged the use of cleaner and sustainable alternatives. Wood from trees represents a sustainable natural resource that has the potential to lock up carbon from the atmosphere and act as a feedstock for the synthesis of fuels and other novel chemicals and materials.^{2,3,9} Although the woody secondary cell wall contains a high proportion of carbohydrates, the presence of the phenolic polymer lignin makes the cell wall recalcitrant to breakdown.¹⁰ Consequently, chemical treatments are used prior to cellulose hydrolysis, increasing the expense and carbon footprint. Lignin biosynthesis has also been altered genetically,^{6,11,12} and labile bonds have been introduced to make lignin more susceptible to breakdown;⁸ however,

these strategies rely on genetic modification and must overcome both public hostility and regulatory hurdles that have prevented the growth of genetically modified trees in many parts of the world.^{13,14}

Apple trees infected with apple rubbery wood (ARW) disease exhibit abnormally flexible branches (Figures S1A and S1B). The disease is associated with the presence of apple rubbery wood virus (ARWV), a negative-stranded RNA virus belonging to the *Bunyaviridae* family.⁵ Although ARW disease was largely eliminated from commercial rootstocks and it is no longer economically relevant, it remains of interest because of the highly unusual symptoms exhibited by infected trees. We are not aware of any other virus causing symptoms that are remotely similar to those exhibited by ARWV-infected trees.

Histochemical analysis of sections from uninfected branches shows the blue staining of cellulose by astra blue is masked by the red staining of lignin by basic fuchsin (Figure 1A); however,

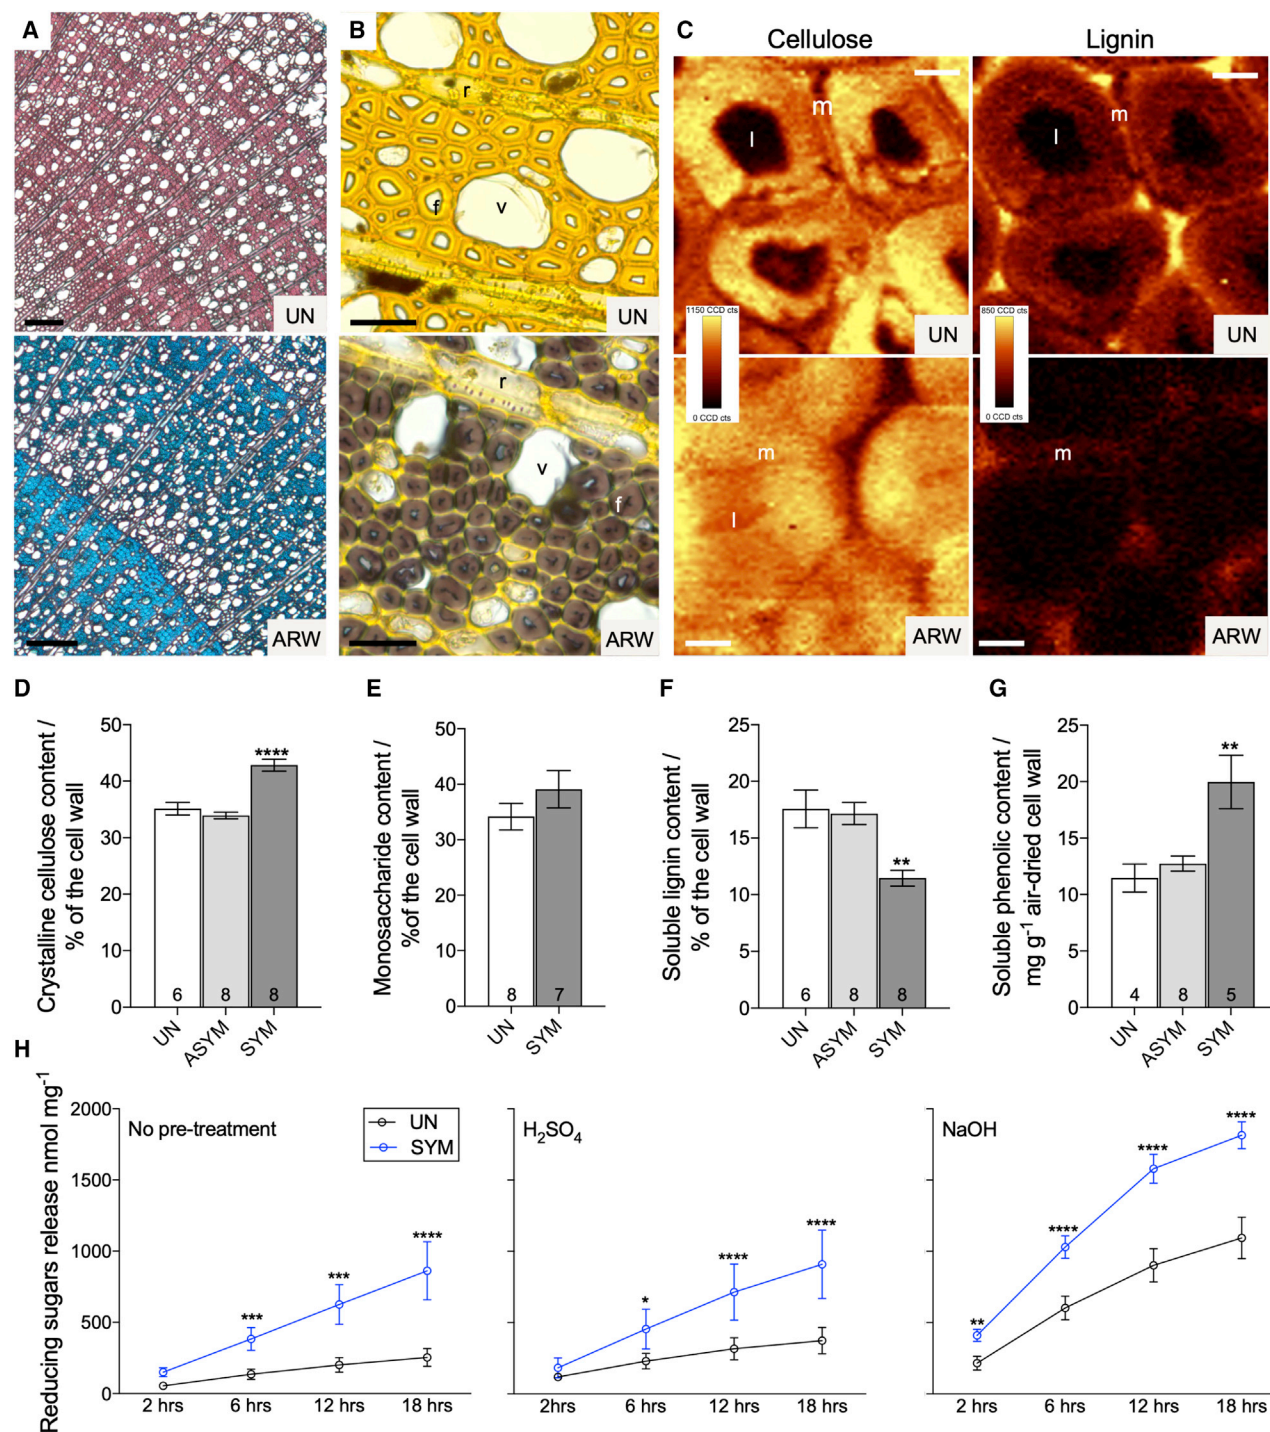

Figure 1. Symptoms of ARWV infection

(A–C) Histochemical staining (A and B) and Raman maps (C) of uninfected (top) and ARWV symptomatic xylem (bottom). Stains are astra blue/basic fuchsin that stains cellulose blue and lignin red (A) and ZnCl_2/KI that stains lignified cell walls yellow and cellulose purple. (C) Raman maps showing the distribution of cellulose and lignin, obtained by integrating the Raman signal between 2,770 and 3,040 cm^{-1} and 1,540 and 1,760 cm^{-1} , respectively. Scale bars indicate 100 μm (A), 25 μm (B), and 3 μm (C). Fibers (f), ray cells (r), vessel (v), cell lumen (l), and mid lamellae (m) are indicated.

(D–G) Cell wall composition of xylem from uninfected (UN), asymptomatic (ASYM), and symptomatic (SYM) ARWV-infected trees. Numbers on individual bars indicate the sample size.

(H) Sugar release from uninfected and symptomatic xylem with either no pre-treatment or pre-treatment with either acid (H_2SO_4) or alkali (NaOH).

(legend continued on next page)

sections from symptomatic pliable branches exhibit strong blue staining suggestive of decreased lignification. In symptomatic xylem, the poorly lignified fibers exhibit secondary cell walls that are much thicker than equivalent fibers from uninfected xylem or from adjacent vessels and ray cells, while the ray cells and mid lamellae of the fiber cells appear unaffected (Figure 1B). Closer examination with transmission electron microscopy revealed that the fiber secondary cell walls are so thick that in mature fibers almost no cell lumen remains (Figure S1D). This phenotype has been previously reported for other plants with altered lignin biosynthesis^{15,16} and results from reduced lignification allowing other components to expand. Vessels also appear somewhat misshapen in symptomatic xylem (Figures 1B and S1D), though they retain an opening that is presumably sufficient for water transport. Furthermore, the thickness of the vessel cell wall is comparable with vessels in uninfected xylem (Figure S1D), suggesting vessel cell walls are largely unaffected. To confirm the histochemical analysis, Raman imaging was used to obtain a high-resolution measure of the distribution of cellulose and lignin. Although lignin is present throughout the cell walls of uninfected xylem, it is largely absent from the secondary cell walls in symptomatic xylem and is limited to the mid lamellae (Figure 1C).

Secondary cell walls in symptomatic xylem exhibit reduced lignin content

In many cases, the presence of symptoms was patchy along the length of the infected branch, and even in the most flexible branches, areas of asymptomatic xylem were still found (Figure S1C). To obtain the most accurate measure of cell wall alterations in symptomatic xylem, symptomatic and asymptomatic regions of the xylem were separated by dissection prior to biochemical analysis. Cell walls from symptomatic xylem had a 22%–26% higher crystalline cellulose content than either uninfected or asymptomatic xylem (Figure 1D). Total non-cellulosic monosaccharide content was marginally increased in symptomatic cell walls (Figure 1E), though the composition was unaltered (Figure S1E). Xylose content, which presumably derives from xylan, the major sugar of woody cell walls in most hardwoods,¹⁷ was similar in uninfected and symptomatic xylem. Acetyl bromide-soluble lignin was reduced by a third in cell walls from symptomatic xylem (Figure 1F). Although this reduction in lignin is larger than previously reported, this likely reflects our use of only symptomatic xylem tissue.¹⁸ Furthermore, the reduction of lignin specifically in the secondary cell walls of the xylem fibers is likely even greater than the 30% reduction in the total xylem. Although lignin content is substantially reduced, the soluble phenolic content of symptomatic xylem was approximately 2-fold higher than in non-symptomatic wood (Figure 1G). A specific decrease in lignin was confirmed by ¹³C solid-state NMR (Figure S1F). Decreases in the heights of peaks with signals at 153, 133, and 56 ppm in the symptomatic spectra demonstrate that syringyl subunits connected by β-O-4 linkages and methoxyl groups of lignin monomers were reduced in symptomatic

cell walls (Figure S1F). The reduction of lignin caused a proportional increase in the spectra for the remaining cell wall polysaccharides: cellulose and hemicellulose (Figures 1D and 1E).

Altered lignin can improve the yield of sugar released from cellulose hydrolysis.^{6,19} Consequently, we assessed the digestibility of symptomatic xylem by measuring reducing sugars released by cell-wall-degrading enzymes. After 18 h, symptomatic xylem yielded 3-fold more sugar than uninfected xylem (Figure 1H). Pre-treatment with alkaline, but not acid, further enhanced sugar release. The quantity of sugar released from untreated symptomatic xylem was similar to that released from NaOH-treated uninfected xylem (Figure 1H). Reduced lignification of symptomatic xylem fibers was most likely the predominant factor that enhanced cellulose.¹⁹

PAL gene expression and protein abundances are reduced in symptomatic xylem

We performed RNA-sequencing analysis on RNA from newly differentiating symptomatic and uninfected xylem. Using a false discovery rate (FDR) adjusted p value < 0.01 and a log-fold change, ±2, 668 genes were differentially expressed (Table S1). Various genes involved in lignin biosynthesis were differentially expressed in symptomatic xylem. There are 6 predicted *PAL1* genes in apple; however, *PAL1A* and *PAL1B* are the most abundant in xylem and both are significantly downregulated in symptomatic xylem (Tables 1 and S1). In contrast, homologs of *4CL*, *COMT1*, *F5H*, *CAD*, and *CHORISMATE MUTASE 2* were upregulated in symptomatic xylem (Tables 1 and S1).

Proteomic analysis using the same material used for RNA-sequencing indicated that 111 proteins exhibited a greater than 2-fold change in abundance with a p value ≤ 0.05 (Table S2). 8 of these 111 proteins were associated with phenylpropanoid metabolism (Table 1). *PAL1A* and *PAL1B* exhibited a reduction in protein levels in symptomatic xylem of 13 and 11 fold, respectively, (Table S2), a slightly larger reduction than that seen for gene expression (Table 1). Strong reduction of *PAL1* indicates that the first committed step in lignin biosynthesis may be compromised during ARWV infection. Peptides corresponding to caffeic acid 3-O-methyltransferase (*COMT*), another enzyme involved in lignin biosynthesis, were reduced by 2-fold in symptomatic xylem even though *COMT1* gene expression was over 8-fold higher (Table 1) and is the likely cause of reduced syringyl lignin in symptomatic xylem (Figure S3). Homologs of *LAC15*,²⁰ *PRX25*,²¹ and *PRX52*²² that are involved in polymerizing monolignol subunits in *Arabidopsis* were significantly more abundant in symptomatic xylem (Table 1).

Alteration in phenylpropanoids in symptomatic xylem is consistent with PAL downregulation

Of the approximately 2,774 profiled compound ions detected, 28 had a 2-fold change in abundance with a p value ≤ 0.001 and an average abundance of at least 100 in either uninfected or symptomatic xylem (Figure 2; Table S3). Several oligolignols

Comparisons were made using a one-way ANOVA and Tukey's multiple comparison test (D–G) or a two-way ANOVA and a Sidak's multiple comparison test (H). Asterisks indicate significance (p > 0.05, *p ≤ 0.05, **p ≤ 0.01, ***p ≤ 0.001, ****p ≤ 0.0001). Bars show standard error of the mean (D–G) or standard deviation (H).

Fold change (FC) in transcript and protein abundance is expressed in terms of symptomatic xylem relative to uninfected xylem. All genes exhibit significantly altered expression, with an FDR-adjusted p value ≤ 0.01 and $\log_{2}FC \geq 2$. All proteins exhibit significantly altered abundance, with a p value ≤ 0.05 and $FC \geq 2$. Genes and proteins not differentially expressed are indicated by N/A. Values marked with an * have multiple gene IDs because individual proteins could not be distinguished during the proteomic analysis: COMT1 (MD07G1300200, MD01G1229100, MD01G1219000, MD01G1229000, MD07G1209500, MD07G1209700, MD07G1300300, MD07G1301100), LAC15 (MD01G1234900, MD07G1307400, MD07G1308000), and flavonoid 3′-mono-oxygenase (MD06G1201700, MD14G1210700). See also [Figure S2](#) and [Tables S1](#) and [S2](#).

were significantly reduced in symptomatic xylem to less than one-third of their abundance in uninfected xylem ([Table S3](#)). Decreased oligolignols and increased soluble phenolics have been observed previously in plants with altered lignification^{23–25} and are consistent with the defect in symptomatic xylem resulting from a decrease in the flux of phenylpropanoids into lignin biosynthesis.

By lowering the significance threshold to $p \leq 0.01$, we found that the substrate for phenylalanine ammonia lyase (PAL), phenylalanine and *N*-acetylphenylalanine, a potential derivative of phenylalanine, were 18- and 3-fold more abundant in symptomatic xylem, respectively ([Figure 2](#); [Table S3](#)), and they have been found to accumulate in *Arabidopsis* and *Petunia pal* mutants.^{26,27} Two butanedioic acids exhibited the second- and third-largest fold increase in symptomatic xylem ([Figure 2](#)). Neither 2-[hydroxy(phenyl)methyl] butanedioic acid nor 2-[hydroxy(hydroxyphenyl)methyl] butanedioic acid has been previously reported in plants. Both phenylalanine and tyrosine are synthesized from chorismate, either in the chloroplast²⁸ or the cytoplasm²⁹ ([Figure 2](#)). We observed a 5-fold increase in

the expression of *CHORISMATE MUTASE 2* ([Table 1](#)), suggesting increased flux through the cytoplasmic pathway ([Figure 2](#)). The synthesis of phenylalanine via the cytoplasmic pathway occurs via phenylpyruvate (PPY) and hydroxyphenyl pyruvate (HPY) that differ only by the same hydroxyl group distinguishing the two butanedioic acids that accumulate in symptomatic xylem, suggesting that these novel compounds may be synthesized via PPY and HPP ([Figure 2](#)). The downregulation of PAL and the accumulation of phenylalanine and compounds derived from the shikimate pathway intermediates are all consistent with the suppression of PAL during ARWV infection ([Figure 2](#)).

Catechin is a well-characterized secondary metabolite that is relatively abundant in apple xylem and is increased by almost 2-fold in symptomatic xylem ([Figure 2](#)). Catechin synthesis requires coumaryl-CoA, a lignin biosynthesis intermediate generated downstream of PAL ([Figure 2](#)). The site of catechin biosynthesis in woody tissue is unknown, but it is unlikely to occur in fiber cells where phenylpropanoid flux is largely directed toward lignin biosynthesis for structural support. Ray cells are a

Figure 2. Potential disruption of phenylpropanoid biosynthesis in symptomatic xylem fibers

Arrows represent enzymatic steps in the shikimate and phenylpropanoid pathways (gray). Dashed arrows coupled with a question mark indicate steps that are uncharacterized in angiosperms. Enzyme names in boxes are involved in the chloroplastic pathway, while enzyme names in italics are involved in the cytosolic pathway for phenylalanine synthesis. In fibers exhibiting ARWV symptoms, the pathway to lignin biosynthesis is inhibited by downregulation of PAL. Those pathways proposed to take place in ray cells, which appear to be unaffected by ARWV, are enclosed by a dashed box. Graphs show mean abundance of metabolites in uninfected (white bars) and symptomatic (gray bars) xylem. Asterisks indicate significance based on a t test (* $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$). Abbreviations are as follows: CM, chorismite mutase; PDH, pyruvate dehydrogenase; PDT, prephenate dehydratase; HPP-AT, hydroxyphenylpyruvic acid aminotransferase; PPA-AT, prephenic acid aminotransferase; PPY-AT, phenylpyruvic acid aminotransferase; ADT, aroenate dehydrogenase; PAL, phenylalanine ammonia lyase; C4H, cinnamate-4-hydroxylase; and 4CL, 4-coumarate-CoA ligase.

The top 24 genes that had the largest fold change in abundance. Both log fold change (FC) and log counts per million (CPM) are expressed in terms of symptomatic xylem relative to uninfected xylem. PAL1A and PAL1B are denoted by *. See also [Tables S4](#) and [S5](#).

more suitable candidate for the site of catechin biosynthesis because they are known to have a more complex metabolism, and while they form lignified secondary cell walls, this process appears unaffected by ARWV infection ([Figure 1](#)).

Symptomatic xylem exhibited a 17-fold reduction in sinapaldehyde together with a significant reduction in syringic acid 4-O hexoside ([Figure S3](#)). Reductions in sinapaldehyde and related derivatives are consistent with the lower abundance of COMT1 proteins in symptomatic xylem ([Table 1](#)) and the reduction of β -O-4 linkages within syringyl subunits in symptomatic xylem ([Figure S1F](#)). Although alterations in COMT1 may alter the lignin subunit composition, it is unlikely to substantially reduce total lignin accumulation.

Downregulation of PAL is a result of virus-induced RNA interference

ARWV possesses only three open reading frames (ORFs) encoding well-characterized viral proteins unlikely to cause specific reductions in PAL.⁵ In several cases, it has been demonstrated that viral symptoms are a result of small interfering RNAs (siRNAs)

generated from the virus being homologous to a gene from the host plant that results in the targeting and downregulation of the gene as part of the plant's defense against the virus.^{30,31} To explore this possibility, we sequenced sRNAs from ARWV-infected and -uninfected grafts, mapped all the sRNA sequences against the ARWV genome, and then remapped them against the apple transcriptome. We identified 54 sRNA sequences that were found in all 4 viral samples with more than 10 reads per sample ([Table S4](#)). The psRNATarget identified 6,888 potential target sites in the apple transcriptome; however, only one sRNA sequence identified 2 PAL genes as potential target sites, albeit with the lowest confidence score and involved only in the inhibition of translation. Consequently, there is no evidence to suggest that siRNAs generated from ARWV are responsible for the decrease in PAL expression.

Virus-activated small interfering RNAs (vasiRNAs) are part of the plant's responses to viral infection.³² These vasiRNAs are generated from several plant genes. vasiRNAs cause widespread silencing of host genes³² and are considered to form part of the host's broad-based antiviral defense. To investigate

vasiRNAs, we mapped the sRNAs directly to the apple genome and identified siRNAs mapping to 125 plant genes that were significantly upregulated in infected tissue (Tables 2 and S5). siRNAs homologous to the 3 *PAL* genes, which we had previously identified as being downregulated during infection (Table 1), exhibited some of the biggest changes in siRNA abundance and were 220 times more abundant in RNA from ARWV-infected xylem (Tables 2 and S5). These vasiRNAs are the likely cause of *PAL* suppression. Why *PAL* would be targeted in this way is unclear. It is possible that some of the novel phenylpropanoid compounds generated may have antiviral properties.

Aside from *PAL*, no other lignin biosynthesis genes or transcripts are downregulated (Table 1), and only *PAL* transcripts are associated with an increased mapping of vasiRNAs genes (Table 2). Consequently, the alteration in lignin appears to be initiated by vasiRNAs that decrease levels of *PAL* mRNA and protein. Changes in the expression and abundance of other mRNAs and proteins associated with lignin and phenylpropanoid biosynthesis are likely to be the result of a feedback mechanism resulting from the decrease in lignin biosynthesis and/or the accumulation of soluble phenolics.

A biomimetic approach to biomass improvement

We are not aware of any other virus that can cause symptoms primarily by altering a major metabolic pathway, such as lignin biosynthesis. Although there has been considerable success in engineering lignin to enhance sugar release,^{8,11,12,33,34} mutants with severe lignin alterations can lead to growth abnormalities,⁶ and this is the case when the *PAL* gene function is knocked out.³⁵ The normal growth of ARWV-infected apple trees is likely a result of the lignin alterations being largely confined to the xylem fibers, as xylem vessels retain a distinct lumen suitable for water transport and do not exhibit the severely collapsed vessels exhibited in some plants with altered lignification.¹⁶ Similarly, the normal plant yield can be maintained when lignin biosynthesis is reduced in fibers only as opposed to all cell types.³⁶

The variable nature of ARW disease means that infected trees are of little value in generating improved wood. However, revealing the molecular mechanism underlying ARWV symptoms offers an opportunity to improve the woody properties of commercially important trees by effectively copying the mechanism by which the virus induces symptoms. Using RNAi or CRISPR to downregulate *PAL* should reproduce the ARWV symptoms in woody trees. Further support for the feasibility of this approach comes from a study in poplar that revealed that *PAL* downregulation using RNAi gave the largest reductions in lignin with only limited impact on growth.⁷

Finally, widespread genetic engineering of many plants is limited by regulatory hurdles and public opposition, and this appears particularly true for trees.^{13,14} It is apparent, however, that technologies considered as new and under regulatory oversight exhibit similarities to events considered to occur naturally. For example, the genome sequence of sweet potato revealed a T-DNA insertion resulting from a historic *Agrobacterium* infection. This insertion was limited to domesticated varieties and presumably confers some trait that was beneficial for domestication.³⁷ Here, we show that the mechanism of siRNAs interference used by the virus shares many similarities to mechanisms of RNAi and antisense that have been used more recently to

genetically engineer lignin.⁷ A long history of safe use is an important criterion used to assess the risk associated with any novel plant variety. ARWV is now largely, if not totally, eliminated from commercial apple trees; however, an extensive survey in the UK during the 1950s when ARWV was widespread revealed that in some cases, over 50% of apple trees sampled were infected with ARWV.³⁸ Since the disease was present across the globe for several decades,³⁹ even conservative estimates would suggest that many thousands of infected apple trees were propagated, and millions of apples from ARWV-infected trees were eaten with no known adverse health or environmental consequences despite the siRNA-induced alterations in lignin caused by the plant's response to the virus.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- **KEY RESOURCES TABLE**
- **RESOURCE AVAILABILITY**
 - Lead contact
 - Materials availability
 - Data and code availability
- **EXPERIMENTAL MODEL AND SUBJECT DETAILS**
 - Plant material and growth conditions
- **METHOD DETAILS**
 - Bright field microscopy
 - Isolating symptomatic xylem
 - Electron microscopy
 - Cell wall sugar analysis
 - Digestibility assay
 - Raman imaging
 - Lignin content
 - Solid-state nuclear magnetic resonance
 - Metabolomic analysis
 - RNA-Sequencing
 - Proteomic analysis
- **QUANTIFICATION AND STATISTICAL ANALYSIS**

RESOURCE AVAILABILITY

Lead contact

Further information and requests for resources, reagents and datasets should be directed to and will be fulfilled by the lead contact, Professor Simon Turner (simon.turner@manchester.ac.uk)

Materials availability

Apple tree material used in this study will be made available upon request without any restriction.

Data and code availability

- RNAseq and sRNAseq datasets have been deposited at ArrayExpress, the proteomic dataset has been deposited at ProteomeXchange, and the metabolomic dataset has been deposited at Metabolights, and are all publicly available as of the date of publication. Accession numbers are listed in the [key resources table](#). All other datatypes in this paper will be shared by the [lead contact](#) upon request.
- No code was generated in this study.
- Any additional information required to reanalyze the data reported in this paper is available from the [lead contact](#) upon request.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Plant material and growth conditions

Apple stem material was propagated from 2 uninfected and 2 ARWV-infected Lord Lambourne apple trees, which were provided by the East Malling Research Station, Kent, UK in 1996. Budwood was grafted onto M27 rootstocks using the ‘whip and tongue’ grafting method⁴⁸ in April 2017. Grafts were kept in a glass house at 22°C and one-year old stem material was harvested the following year for analysis.

METHOD DETAILS

Bright field microscopy

Fresh apple stem material was cut between nodes into approximately 1.5-inch segments and then divided longitudinally into smaller, more manageable segments using a razor blade. 10 μ m transverse segments were cut using a sliding RM2155 microtome. Cross sections were briefly stained with the Herzberg stain [6% iodine, 14% potassium-iodide dissolved in a saturated ZnCl₂ solution (w/v)] directly on the slide⁴⁹ or 0.05% Toluidine blue (w/v). For basic Fuchsin/Astra-blue staining, sections were sequentially stained with 1% basic Fuchsin dissolved in 50% ethanol, followed by 10% Astra Blue pH 2.5 dissolved in 100% ethanol. Stained sections were imaged immediately using a Leica 5500 microscope with a Spot RT3 camera. Sections shown in [Figure 1](#) are representative of more than 400 toluidine blue stained sections from uninfected and ARWV-infected trees taken over 4 successive growing seasons from more than 100 different grafts. For Herzberg staining, more than 100 ARWV-infected and 50 uninfected samples were sectioned and for Astra blue staining, 4 symptomatic and 4 uninfected sections were examined. Electron micrographs are representatives of sections from blocks from more than 10 uninfected and 10 symptomatic samples.

Isolating symptomatic xylem

To dissect symptomatic xylem from asymptomatic xylem, branches were firstly cut between nodes into smaller segments. Each cut branch segment was then sectioned on either side and stained with 0.05% Toluidine blue to assess the distribution of symptoms along the internode. Using the images as a guide, symptomatic regions were isolated from the branch segment with a razor blade and the ends of the branch segment were then re-sectioned and stained to confirm the removal of all the asymptomatic regions. If both sections showed only symptomatic regions, the whole branch fragment was regarded as entirely symptomatic. For nucleic acid and metabolite extraction, sample were enriched for newly differentiating xylem by scraping from symptomatic regions following the removal of the bark.

Electron microscopy

Segments cut from fresh apple stem material were immediately placed in fixative [2% glutaraldehyde, 2% paraformaldehyde dissolved in 0.1 M HEPES buffer, pH 7.2, (v/v)], vacuum infiltrated and then incubated overnight at 4°C. Fixed stem material was stained for two hours in 2% reduced osmium dissolved in 0.1 M sodium cacodylate, pH 7.2 (v/v), followed by staining with 1% uranyl acetate overnight. Stained segments were gradually dehydrated with increasing concentrations of ethanol (25%, 50%, 70%, 90%, 100%), followed by acetone, for one hour each. Segments were progressively infiltrated with increasing concentrations of Medium TAAB resin, mixed in acetone (25%, 50%, 75%, 100%) over the course of three days and polymerised at 60°C for 5 days. Ultra-thin sections

were cut with an ultracut microtome using a DiATOME Ultra 45° knife and mounted on 3.05 nm Athene nickel with a 0.3% formvar coating. Grids were examined on a Tecnai T12 BioTWIN transmission electron microscope and photographed with an Orius CCD SC1000 camera.

Cell wall sugar analysis

Uninfected, asymptomatic and symptomatic xylem segments were sliced thinly with a razor blade, flash frozen in liquid nitrogen and stored at -80°C. Frozen material was freeze dried for 24 hours and then ground into a fine powder using a TissueLyser II for 10 minutes at 1/24 Hz. Cell walls were isolated and de-starched according to Zhang and Zhou.⁵⁰ 100 mg of ground freeze-dried material was mixed with 70% ethanol, 1:1 chloroform/methanol and acetone sequentially and the remaining acetone was left to evaporate overnight in a fume hood. Starch was removed by re-suspending the cell wall material in 5 ml 0.1 M NaOH buffer, pH 5.0, and heating at 80°C for 20 minutes. After cooling on ice, 20 μ l amylase solution (250 μ g/ml) and 5 μ l pullulanase solution was added to re-suspended cell wall material and incubated at 37°C overnight. To stop the reaction, cell walls were heated at 100°C for 10 minutes and centrifuged at 1,300 x g for 10 minutes to pellet the de-starched cell walls. Samples were washed three times with distilled water and once with acetone, leaving the acetone to evaporate.

Crystalline cellulose content was quantified using the Updegraff method using 6 uninfected, 8 asymptomatic and 8 symptomatic samples.⁵¹ Hemicellulose was removed from approximately 10 mg cell wall material by adding Updegraff reagent (glacial acetic acid: nitric acid: water, 8:1:2) and heating samples at 100°C for 30 minutes. Samples were centrifuged for 10 minutes and the supernatant was discarded. Samples were washed with distilled water and acetone sequentially leaving the remainder of the acetone to evaporate overnight in the fume hood. Crystalline cellulose was solubilised into glucose by incubating cell walls with 67% sulphuric acid, overnight on a shaker. To measure glucose content, 0.3% anthrone dissolved in sulphuric acid (v/v) was added to acidified samples or glucose standards, and samples were heated at 100°C for 5 minutes. Absorbance was measured at 620 nm on a spectrophotometer and cellulose content was calculated from a glucose standard curve.

Non-cellulosic monosaccharides were measured with gas chromatography using 8 uninfected and 7 symptomatic samples.⁵² 500 μ l 1 M sulphuric acid was added to approximately 10 mg of cell wall material and incubated at 121 °C for 1 hour. Myo-inositol was added as an internal control. Once cooled, samples were centrifuged for 5 minutes and 250 μ l of the supernatant was added to 100 μ l 9 M NH₃, followed by 1 ml 2% NaBH₄ dissolved in DMSO (w/v), mixed thoroughly and heated at 40°C for 90 minutes. 250 μ l glacial acetic acid was then added, followed by 250 μ l 1-methylimidazole, 4 ml of acetic anhydride, and then briefly mixed. 8 ml of double-distilled water was added, and the samples were mixed until the precipitate dissolved. 1.5 ml dichloromethane was then added and thoroughly mixed, before incubating at 4°C overnight to extract acetylated alditol derivatives. The lower phase was recovered and heated at 55 °C for 45 minutes, or until the filtrate had evaporated. 250 μ l dichloromethane and 1 ml double distilled water was added and vortexed vigorously, to extract hydrophilic compounds into the aqueous phase. When cooled, approximately 200 μ l of the lower phase were analysed on a Supelco SP-2330 column attached to an Agilent 6850 GC instrument. Peaks were assigned by running 20 mg/ml sugar standards (rhamnose, arabinose, xylose, mannose, glucose, galactose and myo-inositol). Monosaccharide content was calculated by dividing the area under each sugar peak with the correction factor determined by the myo-inositol standards.

Digestibility assay

Stem material from 6 uninfected and 6 infected grafts were partially ground with a mortar and pestle under liquid nitrogen and then freeze dried for 48 hours. For each sample, 100 mg was pre-treated with alkali (0.5 M NaOH for 30 minutes at 90°C), a weak acid (0.5% H₂SO₄ for 30 minutes at 90°C), or it received no pre-treatment. All samples were hydrolysed with a Cellulclast:Novozyme 188 enzyme cocktail over 18 hours using an automated platform according to Gomez et al.⁵³ Digestibility was calculated as the adjusted nmol reducing sugars / mg material.

Raman imaging

Thin sections of ~20 μ m were cut on a microtome, placed on a glass slide with a drop of water and cover slip, and the edges were sealed to prevent evaporation. Raman 2-dimensional spectral maps were acquired with a confocal Witec spectrometer equipped with a 514.5 nm (2.41 eV) laser using a backscattering configuration. A 20 μ m x 20 μ m area of cells was selected for Raman scanning. A 100x objective was used, giving a laser spot size of ~200 nm, and the spectral resolution was ≈ 1 cm⁻¹. Spectral images were processed and analysed using WITec Project software v5.3. Raman maps were computed from the spectra by using a sum filter, integrating over the wavenumber range 1540-1780 cm⁻¹ for lignin, and 2830-3040 cm⁻¹ for cellulose.⁵⁴ The images shown are from a region that was deemed to be representative based on screening of toluidine blue stained sections.

Lignin content

Soluble lignin content was quantified from 5 mg de-starched cell wall material using an acetyl-bromide assay, based on the method described by Barnes and Anderson.⁵⁵ Approximately 5 mg cell wall material was incubated with 1 ml 25% acetyl bromide dissolved in acetic acid (v/v) and heated for 4 hours at 50°C. After cooling on ice, 5 ml glacial acetic acid was added and vortexed thoroughly. Residual cell wall material was left to settle overnight at room temperature. 300 μ l of the acetyl-bromide solution was mixed with 400 μ l 1.5 N NaOH and 300 μ l freshly made 0.5 M hydroxylamine hydrochloride. Samples were analysed in triplicate using a microplate reader and the absorbance was recorded at 280 nm. The extinction co-efficient of lignin from *Populus*,⁵⁶ 18.21 g⁻¹ L cm⁻¹, was

used to calculate the lignin content of apple. Analysis was performed on samples from 6 uninfected, 8 asymptomatic and 8 symptomatic grafts,

Solid-state nuclear magnetic resonance

100 mg de-starched cell wall material from an uninfected and symptomatic graft was analysed using CP-MS ^{13}C -NMR spectroscopy, according to Kumar et al.⁵⁷ Briefly, spectra were measured at 100.56 MHz using a Varian VNMRs spectrometer and 4-mm magic angle spinning probe. Cross-polarisation was used to resolve spectra under the following conditions: a 2 second recycle delay, a 3 ms contact time and a spin rate of 10 kHz. The spectra were baseline corrected and normalised so that the total signal for each sample was 100%. In the normalised spectra, peaks were assigned to secondary cell wall polymers based on chemical shifts reported for secondary cell walls in *Arabidopsis*⁵⁸ and various tree species.^{59–61} The spectra shown is derived from pools of uninfected and symptomatic xylem obtained from at least 3 different trees.

Metabolomic analysis

Soluble phenolics were extracted from 10 mg of stem material according to Schenk and Schikora⁶² and measured using the Folin-Ciocalteu method.⁶³ Approximately 10 mg stem material was incubated in 1 ml 80% methanol for 1 hour. The methanol was replaced with fresh methanol and then sample was pelleted, retaining the supernatant as the soluble phenolic fraction. To measure the soluble phenolic fraction, 200 μl of Folin-Ciocalteu reagent was added to 100 μl of the supernatant and gallic acid standards. Samples were analysed in triplicate using a microplate reader and the absorbance was recorded at 765 nm and soluble phenolic content was measured from a gallic acid standard curve. For metabolomics analyses, 7 uninfected and 7 infected graft segments were used. After removing the bark, whole xylem segments were flash frozen in liquid nitrogen. Newly differentiating xylem was scraped from frozen xylem segments and then ground into a fine powder using a mortar and pestle with liquid nitrogen. 50 mg of frozen xylem was incubated with 1 ml methanol for 30 minutes at 128 rpm. Samples were centrifuged for 2 minutes and the methanol fraction was dried for two hours using a speed vacuum. The pellet was re-dissolved in 200 μl water / cyclohexane (v/v) and 10 μl of this aqueous phase was analysed by reverse phase UltraHigh Performance Liquid Chromatography (Waters Corporation) with negative ion ElectroSpray Ionization-Quadrupole-Time-Of-Flight-Mass Spectrometry (ESI-Q-TOF; Waters Corporation). Integration and alignment of the m/z features were performed using the Progenesis Q1 software v2.1. Instrument settings and data processing parameters were as described in Desmet et al.⁶⁴ Structural characterization was performed using in-house developed characterization algorithms and databases^{64,65} combined with CSI:FingerID.^{66,67} Metabolomics data will be deposited at Metabolights (<https://www.ebi.ac.uk/metabolights/>).

RNA-Sequencing

Total RNA was extracted from the same material used for the metabolomics analysis, using the RNeasy PlantPower kit, as per the manufacturer's instructions. DNA was removed using the DNase Max kit and RNA quality and purity was determined using the Agilent 4200 TapeStation. 500 ng of total RNA from 6 uninfected and 6 infected graft segments were sequenced by Illumina HiSeq4000 using 75 bp paired-end sequencing. Raw sequences were mapped to the *Malus x domestica* GDDH13 v1.1 genome and genes were annotated⁶⁸ using the RNA-sequencing aligner, STAR.⁴² Differential gene expression was calculated using DESeq2 and the threshold significance was set at an FDR-adjusted p-value ≤ 0.01 and a log-fold change ± 2 . Gene descriptions were added based on the homology of *M. domestica* transcript sequences with the NCBI non-redundant protein database, which was obtained from the online *M. domestica* genome resource (www.rosaceae.org).

Small-RNA was extracted from 140 ng total RNA and the libraries were assembled using the NEBNext Small RNA Library Prep set for Illumina according to the manufacturer's instructions. 1.9 nM small-RNA libraries were sequenced by Illumina NextSeq using 50 nucleotide single end reads. All raw reads were processed using a maintained version of the Galaxy server.⁴⁵ The adaptors were then trimmed using Trim Galore (www.bioinformatics.babraham.ac.uk/projects/trim_galore) and size selected for reads of 19–25 nucleotides. Trimmed sequences were mapped to the ARWV genome using Bowtie1,⁴⁵ which allowed only exact matches within the seed. Sequences that mapped at least 10 times in each ARWV-infected sample were then used as input for target site analysis, using the psRNatarget analysis server.⁴⁰ Mapping of sRNAs to the GDDH13 v1.1 genome⁶⁸ was performed using HiSat2⁴⁶ and Htseq-count.⁴⁷ Differential expression was calculated using EdgeR,⁴⁴ filtering on low counts to include genes that had a minimum of 10 reads in at least 3 samples.

Proteomic analysis

Proteins were extracted from the same material used for metabolomics, with a 1X SDS-based buffer (1.05% SDS, 32.9 mM Tris-HCl pH 8, 13.15% glycerol, 50 mM DTT). Extraction buffer was added to ground stem material in a 5:1 ratio, and then samples were heated for 10 minutes at 65°C. Extracts were centrifuged for 10 minutes at 3,000 $\times g$ and the liquid phase was retained. 75 μg from each sample was purified and bound to an S-Trap micro column and digested with 5 μg trypsin, according to the manufacturer's instructions. Peptides were eluted with 40 μl 50mM TEAB, 40 μl 0.2% formic acid and 35 μl 50% acetonitrile containing 0.2% formic acid. Pooled elutions were dried for two hours using a HETO SpeedVac. Peptides were analysed on a Q-extractive HF mass spectrometer using ESI-QUAD-TOF. Peptide libraries were normalised to the total amount of protein and peaks were labelled based on the top 3 MS/MS spectra using Progenesis Q1 for proteomics. Using the MS/MS ions protein IDs were assigned using the *M. domestica* genome v1.1⁶⁸ with MASCOT and differential protein abundance was quantified using Progenesis Q1 for proteomics. The threshold

for significance was set at a minimum 2-fold change that was determined by a minimum of two unique peptides to the protein. Analysis was performed on samples from 5 uninfected and 5 symptomatic samples.

QUANTIFICATION AND STATISTICAL ANALYSIS

Biochemical data were analysed with One-Way ANOVAs combined with Tukey multiple comparison tests in GraphPad Prism v9.0.0 and significance values are indicated on [Figures 1](#) and [S1](#). RNA-seq and sRNA-seq data was analysed using DESeq2 and EdgeR respectively, in RStudio v1.1453. Proteomic data was analysed using Progenesis Q1 for proteomics and metabolomics data was analysed using Progenesis Q1 v.2.1 Further information for RNA-seq, sRNA-seq, proteomics and metabolomics analysis is provided in the results and discussion, and STAR methods sections. Sample sizes and confidence intervals for all experiments are indicated in the relevant figures and STAR methods sections. All graphs were generated in GraphPad Prism v9.0.0, chemical structures were created in ChemSketch and biochemical pathways were constructed using InkScape.
