### ABSTRACT

Radicals and their precursors play a central role in the chemical transformations occurring in indoor air and on indoor surfaces. Such species include OH, HO<sub>2</sub>, peroxy radicals, nitrous acid, reactive chlorine species, NO<sub>3</sub>, N<sub>2</sub>O<sub>5</sub>, Criegee intermediates, and glyoxal and methylglyoxal. Recent advances on instrumental analysis and modeling studies have demonstrated the need for a wider range of measurements of radical species and their precursors in indoor air. This work reviews measurement techniques and provides considerations for indoor measurements of several radicals and their precursors. Techniques to determine the actinic flux are also presented owing to the relevance of photolytically-initiated processes indoors. This review is also intended to provide pointers for those wanting to learn more about measurements of radicals indoors.

### KEYWORDS

Criegee; peroxy; HONO; FAGE; CIMS; Laser-induced fluorescence

## 1. Introduction

A small group of highly reactive species, often radicals and their precursors, play a central role in the chemical transformations occurring in indoor air and on indoor surfaces. Reactions involving these species affect indoor air quality through the loss of reactants and the formation of new chemical species whose toxicity could differ substantially from their precursors. Since reaction products are often of lower volatility than their parent compounds, these reactions can also lead to the growth or formation of particulate matter.

Measuring the concentrations of highly reactive species is challenging for several reasons:

- mixing ratios in indoor air are often extremely low
- inlet losses can be problematic. Instrument residence times and material selection are therefore important considerations
- pre-concentration is not generally viable as a measurement strategy as it is with stable organic compounds
- instrument calibration and validation studies are complicated by the absence of commercially available reference materials

Moreover, practical issues like instrument size, noise, and hazards associated with lasers and electrical cables need to be considered in occupied indoor spaces.

Based on the assumption that indoor radical concentrations were much lower than outdoors, the study of reactive indoor chemistry was initially restricted to ozone chemistry. However, first modeling and then experimental studies began to question this assumption and indicated that concentrations of radicals can be on the same order of magnitude as that observed outdoors, or even larger for chlorine radicals under circumstances such as cleaning. Indoor radicals can derive from sources indoors (such as cleaning or air-freshener use) or through infiltration of radical precursors (VOC, O<sub>3</sub> and NO<sub>x</sub>) from outside air.

Transmission of UV and visible light into buildings plays a fundamental role in the generation of radicals. Outdoors, oxidation is driven by photochemistry, often initiated by sunlight at wavelengths shorter than 320 nm. Such high energy photons are not generally available indoors and the oxidizing capacity can be dominated by infiltration of reactant species from outdoor air and by non-photochemical reactions (also known as “dark chemistry”) <sup>[1]</sup>. This results in different oxidizing atmospheres indoors and outdoors.

Recent studies suggest that photolysis of molecules that absorb light at wavelengths longer than 320 nm, such as nitrous acid (HONO) and formaldehyde (HCHO), may lead to higher indoor hydroxyl radical (OH) concentrations than previously expected. Gomez Alvarez et al.<sup>[2]</sup> provided the first direct experimental confirmation that the indoor levels of OH radicals are comparable to outdoor concentrations. Particularly noteworthy are activities that lead to high indoor concentrations of these species, such as of HONO following combustion<sup>[3]</sup>. HONO photolysis can compensate for the missing OH formation by ozone photolysis, which is normally the dominant source of OH radicals outdoors.

Indoor cleaning can also lead to radical production. Carslaw et al.<sup>[4]</sup> reported measurements of OH and hydroperoxy (HO<sub>2</sub>) radicals made by laser-induced fluorescence spectroscopy in a computer classroom, (i) in the absence of indoor activities, (ii) during desk cleaning with a limonene-containing cleaner and (iii) during operation of a commercially available “air cleaning” device. In the unmanipulated environment, the one-minute averaged OH concentration remained close to or below the limit of detection ( $6.5 \times 10^5$  molecules cm<sup>-3</sup>), while HO<sub>2</sub> was  $1.3 \times 10^7$  molecules cm<sup>-3</sup>. These concentrations increased to  $\sim 4 \times 10^6$  and  $4 \times 10^8$  molecules cm<sup>-3</sup>, respectively during desk cleaning. During operation of the air cleaning device, OH and HO<sub>2</sub> concentrations reached  $\sim 2 \times 10^7$  and  $\sim 6 \times 10^8$  molecules cm<sup>-3</sup>, respectively.

Owing to the presence of O<sub>3</sub> and nitrogen dioxide (NO<sub>2</sub>) indoors and the relatively low light levels, it might be expected that the nitrate radical (NO<sub>3</sub>) could attain

significant indoor concentrations. Arata et al.<sup>[5]</sup> conducted direct indoor measurements of the nitrate radical ( $\text{NO}_3$ ) and dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ) produced following combustion cooking emissions in a residential kitchen. They concluded that indoor combustion suppresses nitrate radical chemistry when  $\text{O}_3$  concentrations are low, but at moderate  $\text{O}_3$  levels ( $\sim 40$  ppbv), measured  $\text{NO}_3$  concentrations reached 3–4 pptv. A box model showed that moderate  $\text{O}_3$  levels led to a nitrate radical production rate of  $7$  ppbv  $\text{h}^{-1}$ .

It has also recently been shown that cleaning activities using chlorine-based cleaners including use of bleach can lead to the formation of numerous reactive chlorine (Cl) species, many of which are photo-labile and could generate atomic Cl indoors. Wong et al.<sup>[6]</sup> measured concentrations of chlorinated gases and aerosol components using online chemical ionization and aerosol mass spectrometers after an indoor floor was repeatedly washed with a commercial bleach solution. Gaseous chlorine ( $\text{Cl}_2$ ) at mixing ratios of tens of ppbv and hypochlorous acid (HOCl) at mixing ratios of hundreds of ppbv were observed after floor washing. Nitryl chloride ( $\text{ClNO}_2$ ), dichlorine monoxide ( $\text{Cl}_2\text{O}$ ), and chloramines ( $\text{NHCl}_2$ ,  $\text{NCl}_3$ ) were also formed under these conditions. Photochemical box models indicated that OH, Cl, and chlorine monoxide (ClO) gas-phase radical concentrations could be greatly enhanced ( $>10^6$  and  $10^5$  molecules  $\text{cm}^{-3}$  for OH and Cl, respectively) in such bleach cleaning conditions, depending on the amount of indoor illumination<sup>[6]</sup>. Dark chemistry during bleach cleaning and use of surface disinfectants also affects indoor air quality by enhancing oxidation of organics and production of secondary organic aerosols indoors<sup>[7,8]</sup>.

Gandolfo et al.<sup>[9]</sup> provided direct measurements and modeling of the actinic flux and photolysis frequencies of species relevant for indoor atmospheres (HONO,  $\text{NO}_2$  and  $\text{NO}_3$ ) during summer and winter periods. Zhou et al.<sup>[10]</sup> measured wavelength-resolved ultraviolet (UV) irradiance in multiple indoor environments and quantified the effects of variables such as light source, solar angles, cloud cover, window type, and electric light color temperature on indoor photon fluxes. They reported mathematical relationships that predict indoor solar UV irradiance as a function of solar zenith angle, incident angle of sunlight on windows, and distance from windows and surfaces for direct and diffuse sunlight. Using these relationships, they predict elevated indoor steady-state OH concentrations ( $0.80\text{--}7.4 \times 10^6$  molecules  $\text{cm}^{-3}$ ) under illumination by direct and diffuse sunlight and fluorescent tubes near windows or light sources. In a later study, Zhou et al.<sup>[11]</sup> made intensive measurements of wavelength-resolved spectral irradiance in a test house during the HOMEChem campaign and reported diurnal profiles and two-dimensional spatial distribution of photolysis rates ( $J$ ) of several important indoor photolabile gases. Their results showed that sunlight transmitted through windows, which was the dominant source of ultraviolet (UV) light in the test house, led to clear diurnal cycles and large time- and location-dependent variations in local gas-phase photochemical activity. Compared to diffuse sunlight, local  $J$  values of several key indoor gases under direct solar illumination were 1.8–7.4 times larger and strongly dependent on time, solar zenith angle, and incident angle of sunlight relative to the window. Photolysis rates were highly spatially heterogeneous and fast photochemical reactions in the gas phase were generally confined to within tens of centimeters of the area exposed to direct sunlight. Opening windows increased UV photon fluxes by a

**Figure 1.** Photon flux of common indoor light sources (right axis, arbitrary scale) shown with the product of absorption cross section and photolysis quantum yield of likely indoor oxidants (left axis). Actinic fluxes of the indoor lamps were measured at a short distance. Reproduced from Young et al.<sup>[1]</sup>, with permission from the Royal Society of Chemistry.

factor of 3 and increased predicted local hydroxyl radical (OH) concentrations in the sunlit region by a factor of 4.5, leading to a concentration of  $3.2 \times 10^7$  molecules  $\text{cm}^{-3}$  as a result of higher  $J$  values and an increased contribution from  $\text{O}_3$  photolysis. **Figure 1** displays photon fluxes of indoor light sources and the product of absorption cross section and photolysis quantum yield of likely indoor oxidants.

The above overview of recent measurements and modeling studies demonstrates the need for a wider range of measurements of radical species and their precursors in indoor air. This paper therefore focuses on reviewing measurement techniques and provides considerations for indoor measurements of OH,  $\text{HO}_2$ , and peroxy radicals, OH reactivity, the OH radical precursor, nitrous acid, reactive chlorine species,  $\text{NO}_3$  and its atmospheric reservoir  $\text{N}_2\text{O}_5$ , Criegee intermediates, and the bicarbonyl species glyoxal and methylglyoxal indoors. Techniques to measure the actinic flux are also presented owing to the relevance of photolytically-initiated processes indoors. The inorganic species NO,  $\text{NO}_2$ , and  $\text{O}_3$  were omitted as they are routinely measured relatively straightforwardly.

This review of indoor radicals and radical precursor measurement techniques is intended to provide some pointers for those wanting to learn more about radical concentrations indoors. It is based on recent innovations for radical measurements and connected species/parameters. It is not an exhaustive review of all possible techniques. For instance, Matrix Isolation Electron Spin Resonance (MIESR) has been superseded

**Table 1.** Concentration range of the radicals in the atmosphere. Note that for CH<sub>3</sub>O<sub>2</sub> this represents a model estimate only.

Radical(s)	Atmospheric concentration (molecules cm <sup>-3</sup> )
OH	10 <sup>5</sup> -10 <sup>7</sup>
HO <sub>2</sub>	10 <sup>6</sup> -10 <sup>9</sup>
CH <sub>3</sub> O <sub>2</sub>	10 <sup>6</sup> -10 <sup>8</sup>
sum RO <sub>2</sub>	10 <sup>6</sup> -10 <sup>9</sup>

by other methods and long physical path methods like multi-pass Differential Optical Absorption Spectroscopy (DOAS) are normally too bulky for indoor measurements.

## 2. Measurements techniques of radicals and radical precursors indoors

### 2.1. Hydroxyl and hydroperoxy radicals

Oxidation of volatile organic compounds produces radical species indoors. These gas-phase oxidation reactions transform primary VOC emissions into secondary species (including into harmful pollutants), and involve the OH and HO<sub>2</sub> radicals, collectively known as HO<sub>x</sub>. There is a need to better understand the chemical transformations of multiple VOC species that are present indoors and the potential impact of their oxidation on indoor air quality and human health. Doing so requires the measurement of radical concentrations and the secondary species which derive from them in real-life environments. Such measurements will permit the further development of chemical mechanisms for models and to gain further insight.

Owing to the short-lived nature of radical species (for example, <1 second for OH), their local concentrations are controlled by the rate at which they are chemically formed and removed, and not by transport processes. As a result, comparing measured and modeled concentration profiles of oxidants such as OH radicals is an ideal test of how well we understand the details of these chemical transformations. Another parameter linked to the OH radical is the pseudo-first-order rate coefficient at which OH is removed by its sinks, known as the OH reactivity. This parameter is representative of all the chemical losses of OH. The OH reactivity can be measured in ambient air by coupling a reactor in which OH is generated to instruments able to quantify OH or OH reactivity.

Peroxy radicals, which comprise both HO<sub>2</sub> and organic RO<sub>2</sub> (where R is an organic group), are key intermediate species in the oxidation process. These radicals facilitate fast chemical cycles that reform OH and, in the presence of NO, lead to the formation of NO<sub>2</sub> which can photolyze to generate ozone. The central role of RO<sub>2</sub> and their short lifetimes make measurements of their concentrations useful for comparison with model predictions. However, the measurement of these radicals is an experimental challenge owing to their high reactivity, short lifetimes, and low concentrations. Table 1 summarizes typical concentrations of radicals in the atmosphere, including indoor environments.

A range of instruments have been developed to measure HO<sub>x</sub> radicals in the atmosphere using optical and mass spectrometric techniques [12–14].

**Figure 2.** Techniques currently used to quantify OH in reactive systems: FAGE<sup>1</sup> [15], DOAS<sup>2</sup>[16], Cavity Ringdown Spectroscopy (CRDS)<sup>3</sup> [17], Diode-laser-based UV absorption<sup>4</sup> [18], cw-CRDS<sup>5</sup> [19,20], Cavity-Enhanced Absorption Spectroscopy (CEAS)<sup>6</sup> [21], Diode-Laser wavelength Wavelength Modulation Absorption Spectroscopy (DL-WMAS)<sup>7</sup> [22], Laser-Induced Fluorescence (LIF) (FAGE)<sup>8</sup> [23], diode laser absorption<sup>9</sup> [24], Faraday Rotation Spectroscopy (FRS)<sup>10</sup> [25], CIMS<sup>11</sup> [26].

### 2.1.1. OH quantification

The techniques currently used for OH are Fluorescence Assay by Gas Expansion (FAGE), Chemical Ionization Mass Spectrometry (CIMS) and Differential Optical Absorption Spectroscopy (DOAS), although DOAS is now retired from field use and is only used at one outdoor atmospheric simulation chamber (SAPHIR at Jülich). **Figure 2** shows a range of methods for quantifying OH across a range of concentrations. Techniques based on the measurement of a tracer have been used indoors and in atmospheric simulation chambers (e.g., HIRAC, EUPHORE and SAPHIR).

### 2.1.2. FAGE technique principle

The FAGE (Fluorescence Assay by Gas Expansion) technique is based on detection of Laser Induced Fluorescence (LIF) detection of OH after excitation at 308 nm. The sample is at low pressure, after a gas expansion formed by sampling the atmosphere through a small pinhole. As of 2021, the FAGE technique is the approach most commonly used in field campaigns. Eleven groups in the world have developed instruments: University of Leeds<sup>[27]</sup>, Max Planck Institute in Mainz<sup>[28]</sup>, Forschungszentrum Jülich<sup>[29]</sup>, EUPHORE chamber in Valencia (<http://www.ceam.es/www euphore/>), Pennsylvania State University<sup>[15]</sup>, University of Indiana at Bloomington<sup>[30]</sup>, University of Lille<sup>[31]</sup>, Peking University in collaboration with the Forschungszentrum Jülich<sup>[32]</sup>, and Hefei<sup>[33]</sup>.

Recently, a modification to the FAGE sampling methodology has been made which uses an inlet pre-injector (IPI) to add a chemical scavenger to remove any ambient OH prior to sampling by the pinhole and entering the fluorescence cell<sup>[28,34–36]</sup>. A measurement using the IPI is known as OH-Chem, and is different to OH-Wave, which uses wavelength modulation of the laser to measure the background signal. Through the use of the IPI, any remaining LIF signal from OH must have originated from artificially generated OH from an interference present within the fluorescence cell itself, and

enables removal of this interference signal. OH-Chem and OH-Wave are similar for most conditions.

### 2.1.3. CIMS instrument principle

OH can be converted to  $\text{H}_2\text{SO}_4$  by titration with  $\text{SO}_2$ , with subsequent detection as  $\text{H}_2\text{SO}_4$  using CIMS and ionization based on its reaction with  $\text{NO}_3^-$  ions. As the concentration of OH is low, isotopically labeled  $^{34}\text{SO}_2$  is used to reduce interferences from naturally present  $\text{H}_2\text{SO}_4$ . At present, three groups use CIMS instruments for the quantification of OH in the field<sup>[37–39]</sup>. Isotopically labeled  $^{34}\text{SO}_2$  is very expensive and shortages of it have been known. However, it increases the precision of the measurement as background levels of  $\text{H}_2\text{SO}_4$  can be significant.

### 2.1.4. DOAS instrument principle

DOAS measurement of OH has been developed in the UV (at 308 nm), where the absorption cross sections for OH are large and well known<sup>[16]</sup>. DOAS has the advantage of providing an absolute OH concentration but requires a long absorption path (several km) to reach a sensitivity high enough for atmospheric applications<sup>[40]</sup>. The only current operational instrument for OH measurements is permanently installed in the large SAPHIR chamber in Jülich. The SAPHIR instrument has a multipass cell with a base length of 20 m and a total path length of 2.24 km, giving a limit of detection (LoD) of  $7.3 \times 10^5$  molecules  $\text{cm}^{-3}$  for 200 s integration time<sup>[41]</sup>.

### 2.1.5. OH reactivity

The measurement of OH reactivity has been developed over the last 2 decades for atmospheric applications. This parameter corresponds to the sum of all losses of OH and complements other measurements characterizing the oxidation processes linked to OH. It measures the first order rate coefficient of the OH loss in a single measurement. When compared with model calculations it allows evaluation of whether all the sinks of OH are accurately captured in the chemical mechanism. For this, the directly measured OH destruction rate is compared against the destruction rate inferred from other field measurements. When coupled to the measured OH concentration and to measurements characterizing the major OH-producing pathways ( $\text{HO}_2 + \text{NO}$ , HONO-photolysis and  $\text{O}_3$ -photolysis), it also allows to analyze OH budgets exclusively on experimental data. The overall OH production rate is given by OH-recycling via the  $\text{HO}_2 + \text{NO}$  reaction plus the primary production rates mainly resulting from photolysis of HONO and  $\text{O}_3$ . The overall OH destruction rate is given by the product of total OH reactivity and the OH concentration.

Three techniques have been developed which generate artificial OH in a reactor containing ambient air and measure its decay either directly or indirectly:

1. two are based on OH detection techniques already used for the atmospheric measurement of OH concentrations (FAGE based on the LIF technique, and CIMS) and coupled to different types of reactors: Flow Tube (FT) or Laser

Photolysis reactor (LP) coupled to a FAGE instrument. These two correspond to the following techniques: FT-LIF, FT-CIMS, LP-LIF

2. one based on the measurement of a tracer reacting with OH (Comparative Reactivity Method, CRM)

The FT-LIF method is based on the continuous generation of OH radicals in a flow tube by photolysis of H<sub>2</sub>O vapor by a mercury lamp placed in a moving injector, allowing measurement of OH at different reaction times corresponding to different positions of the injector, with the detection of OH by FAGE<sup>[42]</sup>. Corrections are needed for the recycling of HO<sub>2</sub> (generated simultaneously with OH) into OH in the presence of NO in ambient air.

The LP-LIF is based on detection of OH by FAGE, similarly to FT-LIF, but OH is generated in a reactor by pulsed photolysis of ozone at 266 nm in the presence of water vapor<sup>[43]</sup>. In contrast to FT-LIF, this approach has the advantage of generating only OH, limiting recycling of ambient HO<sub>2</sub> to OH only to high NO conditions. Another advantage is that the OH is directly monitored as a function of time, and conversion from a physical parameter (distance) into time is not required.

The FT-CIMS uses the same OH generation method to FT-LIF but OH is converted first into H<sub>2</sub>SO<sub>4</sub> and detected by CIMS. The measurement is made at one reaction time by alternatively injecting sulfur dioxide in the reactor at the entrance or at a position corresponding to a detection time of about 75 ms<sup>[44]</sup>. Corrections are also needed for recycling of ambient HO<sub>2</sub> into OH with NO.

The CRM technique does not directly measure OH but rather measures a tracer reacting with it. It is based on the competition between the reactions of OH with all species present in ambient air and with the tracer molecule added to the flow. OH is produced in a reactor by continuous photolysis of H<sub>2</sub>O vapor using a mercury lamp and the tracer is quantified by a suitable detector at the exit of the reactor. Pyrrole (C<sub>4</sub>H<sub>5</sub>N) is currently used as the tracer.

The methods used to measure OH reactivity, together with their performance details, are summarized in [Table 2](#). The data in [Table 2](#) is from two intercomparison campaigns of OH reactivity that took place in the atmospheric simulation chamber SAPHIR in Forschungszentrum Jülich in October 2015 and April 2016<sup>[45]</sup>. The intercomparison gathered all the instruments then used for the determination of OH radicals.

The column corresponding to OH concentration in [Table 2](#) is what is generated inside the instrument to perform the OH reactivity measurement. For example, in the LP-LIF method, OH is generated by photolysis of ozone at 266 nm followed by the reaction of O(<sup>1</sup>D) with H<sub>2</sub>O vapor at a certain laser power. The O<sub>3</sub> and H<sub>2</sub>O concentrations vary between instruments and therefore affect the initial OH generated (column [OH] in [Table 2](#)).

### 2.1.6. HO<sub>2</sub> quantification

HO<sub>2</sub> is most frequently quantified by indirect detection based on converting HO<sub>2</sub> to OH and subsequent detection as OH using FAGE or CIMS instruments. However, titration by NO can also convert some RO<sub>2</sub> to HO<sub>2</sub>. In FAGE instruments, modulation of NO is used to selectively detect HO<sub>2</sub><sup>[32,55–57]</sup>. With PerCIMS instruments (Peroxy

Radical Chemical Ionization Mass Spectrometry), depending on the concentration of  $\text{O}_2$ ,  $\text{NO}$  and  $\text{SO}_2$  and diluting the air sampled with either  $\text{O}_2$  or  $\text{N}_2$ , it is possible to speciate measurements of either  $\text{RO}_2$  or  $\text{HO}_2$  <sup>[14,58–60]</sup> but only if  $\text{CH}_3\text{O}_2$  is the major contribution to total  $\text{RO}_2$ . A modified PERCA (peroxy radical chemical amplification) instrument dedicated to the sum of  $\text{RO}_2$  measurement, using detection of  $\text{NO}_2$  by LIF, has been tested to selectively quantify  $\text{HO}_2$  using a denuder with heterogeneous losses higher for  $\text{HO}_2$  than for  $\text{RO}_2$  <sup>[61]</sup>. Bromide has recently been shown to be a useful reagent ion for CIMS detection of  $\text{HO}_2$  with high selectivity and at concentrations relevant to many ambient conditions <sup>[62,63]</sup>. Approaches to measure  $\text{HO}_2$  are shown in Figure 3.

## 2.2. Peroxy ( $\text{RO}_2$ ) radicals

Quantification of  $\text{RO}_2$  radicals is more complex than for  $\text{OH}$  and  $\text{HO}_2$ , because the peroxy radicals comprise a family of radicals and not an individual species. As a result, most techniques only allow measurement of the sum of all  $\text{RO}_2$  or of a sub-group of  $\text{RO}_2$ . Efforts have been made to selectively measure  $\text{CH}_3\text{O}_2$ , the main  $\text{RO}_2$  radical in the atmosphere. Selective quantification of  $\text{CH}_3\text{O}_2$  is possible by titrating with  $\text{NO}$  and detection as  $\text{CH}_3\text{O}$  with laser-induced fluorescence. This approach has been demonstrated in the HIRAC (Highly Instrumented Reactor for Atmospheric Chemistry) chamber<sup>[71]</sup>, where an intercomparison was also performed with the less sensitive cavity-ring down method<sup>[72]</sup>.

Other techniques for unspiciated  $\text{RO}_2$  measurements are based on similar detection methods to those used for  $\text{HO}_2$ , after converting  $\text{RO}_2$  into  $\text{HO}_2$ :

**Figure 4.** Techniques currently used to quantify individual or sum of  $\text{RO}_2$  in reactive systems. Techniques for  $\text{CH}_3\text{O}_2$ : <sup>1</sup>Laser Flash photolysis coupled with UV-time resolved absorption detection<sup>[81]</sup> <sup>2</sup>Time-resolved continuous-wave Cavity Ringdown Spectroscopy<sup>[82]</sup> <sup>3</sup>Vacuum ultraviolet radiation of combined with time-resolved mass spectrometry<sup>[83]</sup> <sup>4</sup>Laser-Induced Fluorescence (LIF)<sup>[71]</sup>. Techniques for sum of  $\text{RO}_2$ : <sup>5</sup>CIMS<sup>[84]</sup>, <sup>6</sup>PerCIMS<sup>[75]</sup>, <sup>7</sup>LIF<sup>[74]</sup>, <sup>8</sup>PERCA<sup>[78]</sup>.

1.  $\text{RO}_x\text{LIF}$  is derived from the FAGE technique, coupling it to a conversion cell held at  $\sim 30$  Torr (addition of CO and NO) to convert  $\text{RO}_x$  ( $\text{RO}_2 + \text{RO} + \text{HO}_2 + \text{OH}$ ) into  $\text{HO}_2$ . Sufficient CO is added so that when OH is formed it is immediately converted to  $\text{HO}_2$ , which is detected in the FAGE after titration with NO<sup>[56,73,74]</sup>. Some speciation of  $\text{RO}_2$  is possible by measuring both the total  $\text{RO}_2$  and the total  $\text{RO}_2$  which gives an interference in the measurement of  $\text{HO}_2$  (mostly larger alkane  $\text{RO}_2$  and  $\text{RO}_2$  derived from unsaturated and aromatic species)<sup>[56]</sup>.
2. PerCIMS is based on the conversion of  $\text{RO}_2$  into  $\text{HO}_2$  and  $\text{HO}_2$  into OH with the detection of OH by CIMS<sup>[75]</sup>.
3. An alternative approach has been developed based on amplification/conversion (PERCA, peroxy radical chemical amplifier). PERCA is based on the conversion of  $\text{RO}_2$  into  $\text{HO}_2$  in the presence of a large concentration of CO and NO.  $\text{HO}_2$  is then involved in a chain reaction in which  $\text{HO}_2$  and OH are interconverted leading to the oxidation of NO to  $\text{NO}_2$ , which is then quantified by LIF<sup>[43]</sup>, chemiluminescence<sup>[76]</sup>, CRDS<sup>[77]</sup>, or CAPS (cavity attenuated phase shift spectroscopy)<sup>[78,79]</sup>. Some more recent versions of a PERCA use ethane rather than CO for the chain amplification chemistry<sup>[78,80]</sup>.

Figure 4 summarizes the specifications of these methods.

### 2.3. Nitrous acid, HONO

Nitrous Acid (HONO) is a respirable pollutant known to convert secondary amines *in vitro* to carcinogenic nitrosamines<sup>[85,86]</sup>. In addition, it can directly initiate DNA crosslinks and is expected to have mutagenic properties. Indoors, HONO is formed

following combustion, as well as by heterogeneous dark and photochemical reaction of  $\text{NO}_2$  and is an important radical source indoors. Gómez Alvarez et al.<sup>[2]</sup> experimentally proved for the first time that photolysis of HONO was possible indoors, i.e., that the range of wavelengths that penetrate through windows could photolyze HONO yielding concentrations of OH radicals that were comparable to outdoor levels. Uptake of  $\text{NO}_2$  to indoor surfaces can result in the heterogeneous formation of nitrous acid (HONO) by various mechanisms<sup>[87–90]</sup>.

HONO mixing ratios of up to 100 ppb have been observed indoors<sup>[2,3,91–105]</sup>. The highest values measured are related to combustion processes. Under conditions where a direct source of HONO, such as a combustion appliance, is not active, mixing ratios are typically less than 10 ppb, which is still much higher than in the ambient atmosphere<sup>[2,106]</sup>.

Due to the wide range of reported HONO levels (<1–100 ppb), instruments used for indoor studies should have a large dynamic range. In addition, since the indoor atmosphere can be a very complex reaction mixture including ambient pollutants ( $\text{NO}_x$ ,  $\text{O}_3$ , VOCs), specific indoor pollutants (e.g., cleaning products, air fresheners, cooking emissions) and their degradation products, HONO instruments should be also selective and almost free of interferences. Furthermore, to study fast variations of indoor HONO levels, such as during cooking events, the instruments should have a time resolution at least in the low minutes range. Finally, HONO instruments should be compact to minimize disruption in indoor spaces.

Early studies using simple carbonate denuders or filter techniques did not fulfill all these requirements (e.g.,<sup>[91–95,99,100,102,107]</sup>). These approaches have a low time resolution and are affected by interferences like  $\text{NO}_2$ .

Other indoor HONO studies used a modified  $\text{NO}_x$  analyzer to allow simultaneous quantitative measurements of HONO<sup>[3,92,96,107]</sup>. The HONO inlet of the instrument consists of a gas denuder (GD) channel and a bypass (BP) channel inserted upstream of the  $\text{NO}_x$  analyzer. The GD removes gaseous acids, including HONO, using a sodium carbonate coated annular denuder which does not remove NO and  $\text{NO}_2$ . Air sampled through the BP channel contains  $\text{NO}_2$  and HONO; both molecules are converted to NO by the molybdenum catalyst<sup>[3,103,108,109]</sup>. A Teflon solenoid three-way valve enabled the sampling of GD (NO and  $\text{NO}_2$  only) and BP (sum of NO,  $\text{NO}_2$  and HONO,  $\sum(\text{NO}_x + \text{HONO})$ ) air alternating at 5 min intervals. However, this technique is not very specific since other acidic  $\text{NO}_y$  species (e.g.,  $\text{HNO}_3$ ) besides HONO are also removed by the carbonate denuder.

Večeřa et al.<sup>[101]</sup> used a wetted wall effluent diffusion denuder, in which water flows down on a modified interior wall of a borosilicate glass tube while sample air moves upward in countercurrent flow. The effluent liquid was debubbled and the anionic constituents were preconcentrated. The separated ions flowed through a cadmium cell to reduce  $\text{NO}_3^-$  to  $\text{NO}_2^-$ , which was detected by the Griess-Saltzman reaction. Following a 3-minute reaction time, the product dye was detected based on its absorption at 555 nm. For a 50 cm wet effluent diffusion denuder, essentially quantitative collection efficiency was observed for both HONO and  $\text{HNO}_3$ .

Differential Optical Absorption Spectroscopy (DOAS) was used in the first HONO indoor studies<sup>[98]</sup>. DOAS is fast, sensitive and selective, but indoor set-ups are cumbersome since a long path absorption system (like a White cell) is needed for high sensitivity. Thus, this technique has not been used in more recent studies.

High time resolution based on incoherent broadband cavity-enhanced absorption spectroscopy (IBBCEAS) was used for the simultaneous measurements of HONO and NO<sub>2</sub> [110,111]. Duan et al. [111] found measurement precisions ( $2\sigma$ ) for HONO and NO<sub>2</sub> of about 180 and 340 ppt in 30 s, respectively. A field inter-comparison was carried out at a rural suburban site in Wangdu, Hebei Province, China. The concentrations of HONO and NO<sub>2</sub> measured by IBBCEAS were compared with a long optical path absorption photometer (LOPAP) and a NO<sub>x</sub> analyzer (Thermo Fisher Electron Model 42i), and the results showed very good agreement, and good correlation with slopes of  $0.941 \pm 0.0069$  and  $0.964 \pm 0.0042$  for HONO and NO<sub>2</sub> respectively and correlation coefficients ( $R^2$ ) of HONO and NO<sub>2</sub> being  $\sim 0.89$  and  $\sim 0.95$ , respectively. In addition, vehicle deployments were also tested to enable mobile measurements of HONO and NO<sub>2</sub>, demonstrating the promising potential of using IBBCEAS for sensitive, accurate and fast simultaneous measurements of HONO and NO<sub>2</sub> in the future.

Laser-photofragmentation laser-induced fluorescence (LP-LIF) has recently been applied to the indirect measurement of HONO with good sensitivity. The approach taken is to photolyze HONO and detect its OH photofragments. Bottorff et al. [112] have used this approach to measure HONO and OH in forests, urban settings, and indoors.

Mass spectroscopic techniques have been used in a few HONO indoor studies. For example, HONO can be measured with Atmospheric Pressure Interface Chemical Ionization Mass Spectrometry (API-CIMS) using chloride reagent ion chemistry [103]. In a study by Collins et al. [97], HONO was detected indoors using a High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (HR-ToF-CIMS) after reaction with the acetate (CH<sub>3</sub>COO<sup>-</sup>) reagent ion. MS techniques are fast, sensitive, and can be selective when well-designed. The humidity dependence of the sensitivity by formation of water clusters has to be carefully calibrated for the CIMS technique [113]. MS instruments are not compact but still have the potential for standard use in indoor studies.

In more recent indoors studies, the LOPAP (Long-Path Absorption Photometer) has frequently been used for real time measurements of HONO [114–118]. This instrument fulfills the criteria mentioned above: a time resolution of a few minutes, high sensitivity and high dynamic range (from low ppt to ppm level), selective detection and a compact design. Since the instrument uses liquid reagents, it is not well-suited for very long-time network measurements. Table 3 summarizes results from some indoor HONO studies performed in different regions with different techniques and sample integration times (concentration levels, instrumentation used, type of indoor environment and location) using either online measurement techniques or offline analysis of collected samples.

### 2.3.1. HONO intercomparison campaigns

There have been several intercomparison campaigns of HONO measurements and instrumentation and the main findings are summarized in Table 4. This section is to provide general performance parameters for the most relevant instrumental techniques that have been used to quantify HONO concentrations, to aid in the selection of suitable techniques for future campaigns. LOPAP is particularly suitable for the determination of HONO in the indoor environment. It has been subjected to extensive tests through intercomparison exercises and has been compared to absolute techniques, i.e., spectroscopic instrumentation like DOAS, for which deployment in the indoor environment can

**Table 3.** Examples of indoor HONO studies.

Location	Building Type	Avg $\pm$ SD [ppb]	Range [ppb]	Technique	Reference
Reactions of NO <sub>2</sub> with water vapor in indoor environment	Chamber study: Reactivity and kinetics study of NO <sub>2</sub> with water vapor	(0.25 $\pm$ 0.04) ppb HONO min <sup>-1</sup> per ppm NO <sub>2</sub> (first order rate kinetics)	15 ppb HONO per ppm NO <sub>2</sub> (Steady state)	DOAS	[98]

**Table 4.** Intercomparison of analytical techniques/instrumentation for the determination of HONO.

Techniques/Instruments intercompared	Summary of results	Reference
DOAS/Annular Denuder (AD)	Good agreement during night, AD $\gg$ DOAS during day	[122]
DOAS/ AD	Good agreement and correlation, but ca. 0.7 ppb offset	[123]
DOAS/Chemiluminescence	Good agreement	[124]
DOAS/Rotated Wet Annular Denuder (RWAD)	Good agreement during night, AD $\gg$ DOAS during day	[125]
LOPAP/DOAS (EUPHORE)	Good agreement for complex conditions (Diesel exhaust/dark)	[126,127]
Parallel Plate Wet Denuder (PPD) (pH = neutral), (RWAD) (pH =9)	Reasonable agreement, often higher HONO for the RWAD. Higher interferences of the RWAD at high pH and /or incomplete sampling of the PPD at lower pH	[128]
Air-dragged Aqua-Membrane-Type Denuder with Fluorescence Detection/Dry Denuder/DOAS	Reasonable agreement between the fluorescence detection and the denuder, good agreement of fluorescence and DOAS during night, but higher than DOAS during day	[129]
DOAS/LOPAP	Excellent agreement in a smog chamber under complex conditions and in a field campaign (urban background, Milan)	[130]
DOAS/Wet Effluent Diffusion Denuder (WEDD)( PPD)	Reasonable agreement between both instrument, higher HONO by the WEDD during daytime	[131]
DOAS/Mistchamber- Ion Chromatography (IC)	Good agreement during night, Mistchamber $\gg$ DOAS during day	[132]
Stripping coil- (IC)/LOPAP	Good agreement	[133]
DOAS/Stripping coil-absorption photometry (SC-AP)/LOPAP/MC-IC/ Quantum Cascade Tunable Diode Laser (QC-TILDAS)/Ion Drift-Chemical Ionization Mass Spectrometry (ID-CIMS)	Reasonable agreement between the instruments, except for the ID-CIMS which shows significant higher HONO	[134]
Modified LOPAP (solenoid pumps instead of peristaltic pump)/ commercial LOPAP,	Modified LOPAP > commercial LOPAP, potential reason 5 m long inlet of the modified LOPAP	[135]
NitroMAC/LOPAP	Excellent agreement in a smog chamber, NitroMAC > LOPAP in the atmosphere	[136]
Incoherent Broadband Cavity-Enhanced Absorption Spectrometer (IBBCEAS)/LOPAP	Excellent agreement	[111]
Stripping coil-IC/LOPAP/CEAS	Good agreement between all techniques	[137]
RWAD (Monitor for Aerosols and Gases in Ambient Air, MARGA)/LOPAP	MARGA > LOPAP	[138]
Commercial LOPAP/Custom Build LOPAP/2x IBBCEAS/ToF-CIMS	High correlation but significant differences between the instruments, reasons were not clarified, potential spacial variability, different inlet position	[139]

pose significant hurdles. For higher indoor levels (>several hundred ppt) the IBBCEAS technique is also a suitable candidate, since these instruments are also compact, fast and selective.

#### 2.4. Reactive chlorine and precursors

The highly reactive Cl atom is a powerful oxidant of both organic and inorganic compounds and can be an important driver of atmospheric chemistry in both indoor and

outdoor environments. The reactive nature of atomic Cl means that its concentrations are too low to be directly measured in the lower atmosphere. Measurements of chlorine-containing species, however, can give us significant insight into both the scale of atomic Cl oxidation and the production of known respiratory irritants (e.g.,  $\text{NCl}_3$ ).

These chlorinated gas phase compounds can be broadly classified into two groups — either organic/amine or inorganic compounds. Most chlorinated-organic compounds are stable with respect to tropospheric degradation processes (e.g., photolysis and OH reaction), and are either directly emitted or formed as oxidation products of Cl atom reactions with hydrocarbons. In contrast, inorganic chlorine compounds (e.g., HCl, HOCl,  $\text{ClNO}_2$ ) can release Cl atoms during their tropospheric cycling and can be considered Cl atom reservoirs. These inorganic compounds are often formed via heterogeneous processes, which are thought to be important drivers of indoor chlorine chemistry [6,8,140].

Observations of chlorinated organic compounds provide useful information as tracers of Cl atom oxidation of hydrocarbons, and the detection of chloramines is useful both as an indicator of their production mechanisms and their direct health impacts. Measurements of inorganic chlorine compounds are key to improving our understanding of the dominant chlorine production and cycling mechanisms. Much of our understanding of chlorine chemistry comes from the study of stratospheric ozone chemistry, but many of the observational techniques used to study the stratosphere (e.g., satellite differential optical absorption) are not suitable for the indoor environment. However, recent developments in both mass-spectrometry and optical techniques make possible the in-situ study of complex chlorine chemical cycles. Table 5 summarizes in-situ observational techniques that have been, or could be, used for the study of chlorine chemistry in the indoor environment.

## 2.5. $\text{NO}_3$ and $\text{N}_2\text{O}_5$

$\text{NO}_3$  is a major nocturnal oxidant in outdoor air formed through the relatively slow reaction between  $\text{NO}_2$  and  $\text{O}_3$  [149]:

Further reaction with  $\text{NO}_2$  reversibly produces  $\text{N}_2\text{O}_5$ , which acts as a reservoir for  $\text{NO}_3$ :

Rapid photolysis by visible radiation (photolysis lifetime of a few seconds in direct sunlight) suppresses  $\text{NO}_3$  concentrations under daylight conditions.  $\text{NO}_3$  reacts rapidly with unsaturated VOCs and can lead to SOA formation. Heterogeneous hydrolysis of  $\text{N}_2\text{O}_5$  on surfaces of solids or particles is an important loss route for nitrogen oxides, producing nitric acid. Heterogeneous  $\text{N}_2\text{O}_5$  reactions with aerosol and surface chloride produce  $\text{ClNO}_2$ , a photolabile source of Cl and  $\text{NO}_2$ .

Absorption spectroscopy has been the most commonly used approach for detecting  $\text{NO}_3$  based on its intense absorption band at 662 nm, allowing sensitive real-time measurements [150]. For in situ measurements, optical cavities are applied using ringdown or cavity-enhanced absorption spectroscopy. Monochromatic (laser) or broadband light

**Table 5.** Techniques and measurement characteristics for chlorine species.

Technique	Compound/s	Typical Limit of Detection [pptv]	Time resolution (indicative)	Practical considerations	Example reference
Gas chromatography-mass spectrometry	Chlorinated organics (e.g., CFCs, CHCl <sub>3</sub> , CCl <sub>4</sub> )	> 0.5	10 — 30 min	Majority of studies use sampling followed by pre-concentration and off-line analysis, although on-line detection is possible with low time resolution (10 min — 1 h)	[140]
Proton-transfer reaction time-of-flight mass spectrometer	Chloramines (e.g., NHCl <sub>2</sub> , NCl <sub>3</sub> )	1	1 s	Highly sensitive, high time resolution instrument that can simultaneously measure multiple compounds. But instrument is expensive and complicated to calibrate/operate. Note that simultaneous measurements of NHCl <sub>2</sub> and NCl <sub>3</sub> by I-CIMS and PTR by Mattila et al. <sup>[8]</sup> reported concentration discrepancies of several orders of magnitude	[8]
Iodide chemical ionization mass spectrometry (I-CIMS) / time-of-flight CMIS (I-tof-CIMS)		< 10	1 s	Highly sensitive, high time resolution instrument that can simultaneously measure multiple compounds of interest, but instrument is expensive and complicated to calibrate/operate. Also requires radioactive source. Interferences can be issues, especially from small molecules, which can be formed via fragmentation within the instrument. This has been specifically noted for ClO <sup>[8]</sup> .	[6,8]
	Chlorinated oxygenated organics	1	1 s		
	HOCl	30	1 s		
	ClNO <sub>2</sub>	1	1 s		
	Cl <sub>2</sub>	3	1 s		
	Cl <sub>2</sub> O	0.2	1 s		
Chemical conversion resonance fluorescence	ClO	3	1 s	Complex custom instrumentation that is no longer in frequent use.	[141]
		4	16 s		
Laser Absorption spectroscopy	HCl	10	1 s	Relatively simple methodology and optical nature makes it selective. HCl is difficult to sample due to wall effects. Specifications are for instrument presented by Halfacre et al. at EGU 2020. Citation is for an older instrument with significant inlet effects.	[142]
Cavity ring-down spectroscopy		18	30 s	Compact instrument. Humidity dependant response time due to wall interactions	[143]
Off-axis integrated cavity output spectrometer (OA-ICOS)		78	30 s	Compact and lightweight instrument. Has been deployed as part of a stratospheric balloon payload. Has not been demonstrated for tropospheric humidities and artifacts	[144]
Denuder or filter collection		200	30 min— 24 h	Offline analysis method. Poor time resolution but relatively simple	[145]

*(continued)*

**Table 5.** Continued.

Technique	Compound/s	Typical Limit of Detection [pptv]	Time resolution (indicative)	Practical considerations	Example reference
followed by offline ion-chromatography Iodide chemical ionization mass spectrometry (I-CIMS) / time-of-flight CIMS (I-tof-CIMS)		30	30 s	sampling, without the need for large complex in-situ instrumentation See above for I <sup>-</sup> CIMS	[146]
Acetate chemical ionization time-of-flight mass spectrometry		2	1 min	Highly sensitive, high time resolution instrument, but expensive and complicated to calibrate / operate. Acetate ion inlet chemistry also less widely used than I <sup>-</sup>	[147]
SF <sub>6</sub> <sup>-</sup> chemical ionization mass spectrometry		2	30 s	Highly sensitive, high time resolution instrument, but expensive and complicated to calibrate / operate. SF <sub>6</sub> <sup>-</sup> ion inlet chemistry also less widely used than I <sup>-</sup>	[148]

sources may be used. Laser-based methods require additional measures to account for absorption by NO<sub>2</sub> and O<sub>3</sub> and scattering by particles. Inlet filters can be used to remove particle extinction, but must be changed regularly to avoid variable NO<sub>3</sub> losses with aging [151]. The rapid titration of NO<sub>3</sub> with NO:

is often used to establish a baseline extinction.

Broadband methods use spectral analysis over tens of nanometers to retrieve the absorption and hence concentration of NO<sub>3</sub>. Interfering absorptions are identified through spectral fitting; however, water can complicate spectral retrieval because water absorption lines are too narrow to be resolved by a spectrograph and measured spectra diverge from the Beer-Lambert law [152]. Calibrating the response of broadband instruments is also more complex than for CRDS systems. Many outdoor (often airborne) studies now use the optical cavity methodology.

N<sub>2</sub>O<sub>5</sub> is indirectly detected as NO<sub>3</sub> via thermal decomposition at elevated temperatures in the sample inlet. A single, extractive instrument with heated and unheated inlet channels can therefore be used to detect both NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>. Although most optical cavity instruments draw the air sample through an enclosed optical cavity, broadband open path systems based on CEAS may have potential for indoor measurements, although N<sub>2</sub>O<sub>5</sub> quantification is not possible with this configuration [153,154].

Alternative methods include thermal dissociation-chemical ionization mass spectrometry (TD-CIMS) to quantify the sum of NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub> using ionization by the I<sup>-</sup> ion [155,156]. Laser-induced fluorescence detection of NO<sub>3</sub> has been demonstrated to a 1σ sensitivity of about 4 pptv over a 10 min period [157,158]. The LIF is less sensitive than absorption-based methods and has not been extensively pursued for detecting NO<sub>3</sub>/N<sub>2</sub>O<sub>5</sub>. A flow tube reactor combined with adsorbent tube sampling and analysis using

**Table 6.** Measurement type and performance characteristics of instrumentation to measure NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>.

Technique	Compound	Typical Limit of Detection (2σ) [pptv]	Time resolution [s]	Description	Reference
CRDS	NO <sub>3</sub>				[160]
CRDS	NO <sub>3</sub>	0.5	5		[161]

	N <sub>2</sub> O <sub>5</sub>	2.4	24		
BB-CRDS	NO <sub>3</sub>	1	100		[152]
	N <sub>2</sub> O <sub>5</sub>	1	100		
BBCEAS	NO <sub>3</sub>	0.5	10	Open path across chamber, 4 m Open path, 0.84 m cavity length	[163]
IBBCEAS	NO <sub>3</sub>	2.7	60		[153]
	NO <sub>3</sub>	3	30		
IBBCEAS	NO <sub>3</sub>	4	10	Open path across chamber, 0.82 cm cavity length	[164]
	NO <sub>3</sub>	4.6	2.5	Compact, inexpensive, 2 channels for NO <sub>3</sub> & N <sub>2</sub> O <sub>5</sub>	[165]
CRDS	N <sub>2</sub> O <sub>5</sub>	6.2	2.5		
IBBCEAS	NO <sub>3</sub>	3	100	Compact and low-cost instrument. NO <sub>2</sub> & NO <sub>3</sub> detection at 625 nm. LoD is stated as upper limit, but unclear whether LoD defined as 1σ, 2σ, 3σ	[166]
BBCEAS	NO <sub>3</sub>	1.4	1	For airborne measurements. Two channel instrument	[167]
	N <sub>2</sub> O <sub>5</sub>				
Open path IBBCEAS	NO <sub>3</sub>	3	30	Open path system	[154]
TD-CIMS	NO <sub>3</sub> + N <sub>2</sub> O <sub>5</sub>	8	1	Main focus on peroxyacyl nitrates	[155]
TD-CIMS	NO <sub>3</sub> + N <sub>2</sub> O <sub>5</sub>	7	60	Use of I <sup>-</sup> ionization. Used in field	[156]
LIF	NO <sub>3</sub>	76	60		[158]
	N <sub>2</sub> O <sub>5</sub>	76	60		
LIF	NO <sub>3</sub>	8	600		[157]
	N <sub>2</sub> O <sub>5</sub>	12	600		

thermal desorption-gas chromatography was used for the first experimental measurements of indoor NO<sub>3</sub>/N<sub>2</sub>O<sub>5</sub> chemistry but the system is complex and time resolution is poor [159].

Performance characteristics of instruments measuring NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub> are given in Table 6. Instrument intercomparison studies have shown good agreement between the different absorption methods [168,169].

## 2.6. Criegee intermediates

Criegee Intermediates (CIs), also known as zwitterionic intermediates or carbonyl oxides, have been the center of growing interest over the past decade due to their

potential role in the oxidative capacity of the atmosphere and specifically in SO<sub>2</sub> oxidation and secondary aerosol formation.

Outdoor concentrations ranging from 10<sup>4</sup> to 10<sup>5</sup> molecules cm<sup>-3</sup> have been estimated from modeling studies for the sum of atmospheric Criegees<sup>[170]</sup>. This range of values is consistent with indirect observations indicating a mean concentration of approximately 5 × 10<sup>4</sup> molecules cm<sup>-3</sup> during the HUMPPA-COPEC 2010 (forested area) and HOPE 2012 (rural area) field campaigns<sup>[171]</sup>. The pool of atmospheric CIs is complex due to (i) the multitude of unsaturated VOCs that can react with ozone in the atmosphere and (ii) the potential formation of syn- and anti-conformers. Both the complexity of the CI mixture and their presence at low concentrations put stringent demands on analytical techniques in terms of sensitivity and selectivity.

While no technique is currently available for atmospheric measurements of CI, some direct and indirect approaches have been developed in the laboratory to characterize the chemical structure of small CIs (C<sub>1</sub>-C<sub>6</sub>) and to study their kinetics. Techniques for direct detection of specific CIs include photoionization mass spectrometry, spectroscopic approaches in the ultraviolet, infrared and microwave regions, and chemical ionization mass spectrometry<sup>[172,173]</sup>. An indirect technique relying on the stabilization of CIs using spin trap molecules and their subsequent detection by mass spectrometry was also proposed<sup>[174-176]</sup>. In addition to these laboratory techniques, a few instruments designed for hydroxyl radical measurements in the atmosphere have shown potential to detect unspciated CIs<sup>[171,177]</sup>. First, we briefly describe techniques designed to investigate the structure and the kinetics of CIs in the laboratory and we then discuss OH field instruments that may be capable of detecting CIs in the atmosphere.

### 2.6.1. Detection techniques employed in the laboratory for fundamental research

1. *Photoionization mass spectrometry (PIMS)*: Taatjes et al.<sup>[178]</sup> and Welz et al.<sup>[179]</sup> demonstrated that PIMS can be used for detecting individual CIs in simple chemical mixtures. The authors employed the tunable vacuum UV light from the ALS synchrotron at Berkeley National Laboratory to perform kinetic experiments on the simplest CI, formaldehyde oxide (CH<sub>2</sub>OO). A subsequent study from the same group highlighted that some selectivity can also be achieved between anti- and syn-conformers of acetaldehyde-oxide (CH<sub>3</sub>COO) on the basis of their difference in ionization energy<sup>[180]</sup>. This technique was extended to the detection of acetone-oxide ((CH<sub>3</sub>)<sub>2</sub>COO)<sup>[181]</sup>.
2. *UV-Vis absorption spectroscopy*: This technique was used by several groups for the detection of formaldehyde-oxide, acetaldehyde-oxide, methylvinylketone-oxide, and methacrolein-oxide, taking advantage of their specific absorption features<sup>[173,182]</sup>. Sheps et al.<sup>[183]</sup> reported that syn- and anti-conformers of acetaldehyde-oxide can be distinguished in this range of wavelengths. Instrumentation used to monitor CIs during laboratory experiments are single pass cell/LED, multipass cell/Ti:Sapphire laser, CEAS, and CRDS<sup>[173]</sup>.
3. *IR absorption spectroscopy*: Several studies used IR absorption spectroscopy to detect different conformers of acetaldehyde-oxide, acetone-oxide, methylvinylketone-oxide, and methyl-ethyl Criegee intermediate (MECI)<sup>[173,184,185]</sup>. A higher degree of selectivity than in the UV region can be achieved if high-resolution IR

sources are used. The detection of CIs is performed using broadband FTIR, high-resolution CW-QCL, and action spectroscopy [173].

4. *Microwave spectroscopy*: This technique was used under molecular beam conditions to investigate the molecular structure of CIs and their kinetics, including various isotopologues of formaldehyde oxide, syn- and anti-conformers of acetaldehyde-oxide, and acetone-oxide [173].
5. *Spin trap/Chemical Ionization Mass Spectrometry*: Gioro et al. [174,175] proposed an online method relying on the stabilization of CIs using a spin trap molecule (DMPO - 5,5-dimethylpyrroline-N-oxide) and the quantification of the CI-spin trap adducts by Proton Transfer Reaction-Mass Spectrometry (PTR-MS) using  $\text{H}_3\text{O}^+$  reagent ions. Combining high resolution mass spectrometry with the selective nature of the DMPO-CI reaction has the potential to provide the discrimination needed to speciate non-isobaric CIs in complex chemical mixtures. The authors reported detection of CIs generated from ozonolysis of biogenic and anthropogenic alkenes with a detection limit of approximately  $7 \times 10^8$  molecules  $\text{cm}^{-3}$  (10 s integration time) for  $\alpha$ -pinene-derived CIs. More recently, Zaytsev et al. [176] also reported the use of DMPO and other spin trap species (HFA: Hexafluoroacetone, TEMPO: (2,2,6,6-tetramethylpiperidin-1-yl)oxyl) with PTR-MS using  $\text{H}_3\text{O}^+$  and  $\text{NH}_4^+$  reagent ions. The authors reported detection limits for acetone-oxide of  $1.4 \times 10^7$  molecules  $\text{cm}^{-3}$  and  $3.4 \times 10^7$  molecules  $\text{cm}^{-3}$  at a time resolution of 30 seconds using HFA/ $\text{H}_3\text{O}^+$  and DMPO/ $\text{NH}_4^+$ , respectively.
6. *Chemical Ionization Mass Spectrometry*: Berndt et al. [186] demonstrated that CIs can also be directly detected by CIMS as adducts using reagent ions such as protonated ethers (tetrahydrofuran, diethyl ether) for formaldehyde-oxide and protonated amines (n- and tert-butylamine, diethylamine) for cyclohexene-derived C6-CIs. The authors stressed that selective detection of CIs from other isomeric compounds is possible through careful selection of reagent ions. However, selective detection of CIs in the complex mixture of ambient trace gases has yet to be demonstrated. Detection limits ranging from  $10^4$  to  $10^5$  molecules  $\text{cm}^{-3}$  were observed during kinetic experiments using a CI-APi-TOF (Chemical Ionization – Atmospheric Pressure interface – Time Of Flight) instrument at a time resolution of 10 min.

### 2.6.2. Field deployable instruments and atmospheric measurements of CIs

The deployment of instruments capable of measuring the atmospheric hydroxyl radical (OH) has provided surprising observations over the past decades, indicating that species other than OH were detected during specific steps of the OH measurement sequence. Indeed, zeroing approaches implemented by CIMS, [177] and FAGE, [28,171]) instruments have highlighted the presence of reactive species capable of oxidizing  $\text{SO}_2$  in CIMS instruments or capable of producing OH in the low pressure sampling cell of FAGE instruments. Further investigations indicated that the behavior of these unidentified species is consistent with the known CI chemistry, which suggests that a substantial fraction of these unidentified species could be CIs. The extent to which “background” signals from both CIMS and FAGE instruments are connected to ambient CIs is not

clear and further investigation is necessary to determine whether these techniques could be used to provide integrated measurements of the pool of ambient CIs.

While a large number of techniques have been used in the laboratory to characterize the molecular structure of CIs and their kinetics, it will be challenging to transfer these techniques for indoor environments due to the sensitivity and selectivity required. Indeed, these techniques were employed on experimental systems where large concentrations of CIs (likely higher by several orders of magnitude than in the atmosphere) can be generated in simple chemical mixtures, with a lower number of potentially interfering species than in the atmosphere. The most promising approach, which was shown to reach detection limits that are close to estimated ambient CI concentrations, is CIMS<sup>[186]</sup>, which has already been used for monitoring other reactive species such as the hydroperoxyl radical (HO<sub>2</sub>)<sup>[62]</sup> and HOMs<sup>[187]</sup>. The quantification of atmospheric CIs will also require the development of calibration apparatus capable of generating known concentrations of specific CIs<sup>[171]</sup>.

## **2.7. Glyoxal and methylglyoxal**

Photolysis of dicarbonyl compounds, specifically glyoxal (CHOCHO, GLY) and methyl glyoxal (CH<sub>3</sub>C(O)CHO, MGLY), is the main initiation route that produces HO<sub>2</sub> and RO<sub>2</sub><sup>[188]</sup>. This route has been verified several times in the outdoor environment. It also operates efficiently in the indoor environment and can even be enhanced under certain circumstances such as cleaning or use of air cleaners<sup>[4]</sup>. GLY and MGLY are produced in the atmosphere by several processes, including oxidation of VOCs (particularly biogenic species)<sup>[189]</sup>, anthropogenic photo-oxidation of aromatics in the presence or absence of NO<sub>x</sub><sup>[190–195]</sup>, pyrogenic sources<sup>[196–200]</sup>, and via chemical routes such as dicarbonyl formation from Criegee biradicals<sup>[201]</sup>.

The main sources of GLY and MGLY in the indoor environment are diverse, and most of them are also observed outdoors (e.g., oxidation of aromatic species). Other routes more specific to the indoor environment would be formation via metabolic processes since they are formed endogenously in numerous enzymatic and nonenzymatic reactions<sup>[202–207]</sup>. Particularly important to the indoor environment is their formation by ozonolysis of terpenes, found in cleaning products and fresheners. The ozonolysis of squalene is closely related to the presence of occupants because squalene is an important component of human skin oil. Given the high degree of unsaturation in squalene, tertiary and higher-order reaction products can be generated and sequential ozone attack generates bifunctional secondary products that contain carbonyl, carboxyl, or  $\alpha$ -hydroxy ketone terminal groups<sup>[208]</sup>. The major bifunctional products are the four dicarbonyls: 4-oxopentanal (4-OPA), 1,4-butanedial (succinic dialdehyde), 4-methyl-8-oxo-4-nonenal (4-MON), and 4-methyl- 4-octene-1,8-dial (4-MOD) produced by attack at the bonds.

### **2.7.1. Measurement of indoor glyoxal and methylglyoxal**

GLY and MGLY can be measured by various techniques: infrared (IR) absorption spectroscopy<sup>[209,210]</sup>, ultraviolet-visible (UV-Vis) absorption spectroscopy<sup>[211–214]</sup>, chromatographic analysis of derivatization by O-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine (PFBHA) or dinitrophenylhydrazine (DNPH) followed by mass spectrometry or flame

ionization, and phosphorescence <sup>[215,216]</sup>. CIMS (using  $\text{H}_3\text{O}^+$ ,  $\text{O}_2^+$  or  $\text{NO}^+$  reagent ions) has also been used to detect MGLY <sup>[217–220]</sup>.

Most measurements of GLY and MGLY have used derivatisation techniques and a variety of sampling methods with off-line GC analysis with different detectors, GC/MS or HPLC. The most extensively investigated source of GLY and MGLY and other dicarbonyls indoors is from ozonolysis of terpenes in cleaning products, air fresheners, and ventilation systems. Derivatisation techniques have mainly been used for this analysis, and hundreds of papers can be found in the literature on this topic. Table 7 lists example studies that applied derivatization with off-line chromatographic analysis to illustrate the most common sources of GLY, MGLY (and in some studies, several other dicarbonyls) that have been studied in the indoor environment.

Szulejko and Kim <sup>[233]</sup> authored a general review of derivatization techniques for determination of carbonyls in air and provided a list of selected derivatising agents. The most common are O-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride (PFBHA) 2,4-dinitrophenylhydrazine (DNPH). Studies by Ham et al. <sup>[228]</sup> and Jackson et al. <sup>[234]</sup> used TBOX, o-tert-butylhydroxylamine hydrochloride as derivatizing agent. A fluorogenic reagent, dansylhydrazine (DNSH) provide hydrazones that can be analyzed by fluorescence, which enhances the sensitivity and selectivity of the technique. Zhang et al. <sup>[235]</sup> used this method to develop a Personal Aldehydes and Ketones Sampler (PAKS). Other applications have been detection of GLY (and other toxic carbonyl compounds) in cigarette smoke <sup>[236]</sup> by derivatizing reactive carbonyl compounds into stable nitrogen-containing compounds (pyrazoles for  $\beta$ -dicarbonyl and  $\alpha,\beta$ -unsaturated aldehyde; and quinoxalines for  $\alpha$ -dicarbonyls), followed by quantitative detection using gas chromatography with a nitrogen phosphorus detector.

Indoor environments have access obstacles and space constraints that do not influence outdoor measurements. Techniques that have been used for indoor measurements of GLY and MGLY are mostly easy to deploy techniques that do not require bulky equipment or that involve only the sampling of gases or particles followed by offline analysis. There are a few exceptions like the HOMECEM campaign <sup>[237]</sup> or the SURFIN campaign in a school classroom in Marseille <sup>[2]</sup>. For these reasons, the inter-comparison exercises carried out in simulation chambers constitute a useful basis to discuss the different measurement techniques for GLY and MGLY.

Thalman et al. <sup>[238]</sup> carried out an intercomparison of different techniques for the measurement of GLY, MGLY and  $\text{NO}_2$  in the NCAR and EUPHORE chambers (see Table 8). Excellent linearity was attained by all instruments/techniques under idealized conditions (pure GLY or MGLY,  $R^2 > 0.96$ ) and in complex gas mixtures characteristic of dry photochemical smog systems (o-xylene/ $\text{NO}_x$  and isoprene/ $\text{NO}_x$ ,  $R^2 > 0.95$ ;  $R^2 \sim 0.65$  for offline Solid Phase Micro Extraction, SPME, measurement of MGLY). The correlations were more variable at higher humidity ( $\text{RH} > 45\%$ ) for MGLY ( $0.58 < R^2 < 0.68$ ) than for GLY ( $0.79 < R^2 < 0.99$ ). Intercepts of correlations were generally below the instruments' experimentally determined detection limits and slopes varied by less than 5% for instruments that could also simultaneously measure  $\text{NO}_2$ . For GLY and MGLY the slopes varied by less than 12 and 17% (both  $3\sigma$ ) between direct absorption techniques (i.e., calibration from knowledge of the absorption cross section). Larger variability was found among in situ techniques that employed external calibration

**Table 7.** Synopsis of some of the most relevant indoor studies using derivatization followed by off-line chromatographic analysis that have determined glyoxal and/or methylglyoxal as a result of representative indoor activities.

Derivatizing agent	Sampling method	Indoor activity	Precursor	Instrument	Carbonyls/Dicarbonyls detected	Reference
PFBHA	FLEC Automation and Control System (FACS)	Cleaning	$\alpha$ -terpineol + O <sub>3</sub>	GC/MS	GLY, MGLY 4-oxopentanal, 4-methylcyclohex-3-en-1-one, 6-hydroxyhept-en-2-one, 3-(1-hydroxy-1-methylethyl)-6-methylcyclohex-2-en-1-one), 5-(1-hydroxy-1-methylethyl)-2-methylcyclohex-2-en-1-one	[221]
PFBHA	Captured in solution) on glass plate surface)	Skin (emissions due to dwellers)	Squalene + O <sub>3</sub>	GC-Ion Trap Mass Spectrometry	GLY 6-methyl-5-hepten-2-one (6MHO), 4-oxopentanal (4OPA), geranyl acetone, 5,9,13-trimethyltetradeca-4,8,12-trienal	[222]
PFBHA	Samples drawn through a 6.4 mm Teflon Swagelok fitting attached to a 65 L Teflon chamber	Cleaning	$\alpha$ -Terpineol + NO <sub>3</sub> <sup>-</sup>	GC/MS	GLY, MGLY acetone, 6-hydroxyhept-5-en-2-one, 4-(1-hydroxy-1-methylethyl)-1-methyl-2-oxocyclohexyl nitrate, 5-(1-hydroxy-1-methylethyl)-2-oxocyclohexyl nitrate, 1-formyl-5-hydroxy-4-(hydroxymethyl)-1,5-dimethylhexyl nitrate, 1,4-diformyl-5-hydroxy-1,5-dimethylhexyl nitrate	[223]
PFBHA	PDMS/DVB SPME	Cleaning	Citronellol + O <sub>3</sub>	GC/MS	GLY, MGLY acetone, 6-hydroxy-4-methylhexanal	[224]
PFBHA	four bubblers with frits, containing 500 ml acetonitrile each	Ventilation	$\alpha$ -pinene (heterogeneous reactions)	GC/MS in the positive chemical ionization mode using CH <sub>4</sub> as reagent gas	GLY, MGLY Several other carbonyls	[225]
PFBHA	SPME	Cleaning	terpinolene + O <sub>3</sub> , terpinolene + NO <sub>3</sub> <sup>-</sup>	GC/MS	GLY, MGLY, other dicarbonyls (including some very photolabile unsaturated ones)	[226]
DNPB	Silica cartridges	Cleaning	a-pinene, camphene, b-pinene, myrcene, 3-carene, p-cymene, d-limonene, eucalyptol, g-	HPLC/MS	GLY, MGLY formaldehyde, acetaldehyde, acetone, propionaldehyde, 2-butanone (MEK), iso + n-butyraldehyde, benzaldehyde, iso-valeraldehyde, n-	[227]

O-tert-butyl-hydroxyl-amine hydrochloride (TBOX)	Water in Impinger	Cleaning,	terpinene, terpinolene, linalool, a-terpineol	GC/MS	valeraldehyde, o-tolualdehyde, m-tolualdehyde, p-tolualdehyde, hexanal, 2,5-dimethylbenzaldehyde Unsaturated carbonyls: acrolein, crotonaldehyde	[228]
TBOX	Bubbler	3D printer	terpinolene + O <sub>3</sub> , terpinolene + NO	GC/MS	MGLY 4-methylcyclohex-3-en-1-one, (4MCH), 6-oxo-3-(propan-2-ylidene) heptanal (6OPH), 3,6-dioxoheptanal (36DOH). The tricarbonyl 36DOH has not been previously observed.	[229]
PFBHA	Methanol in Impinger	Cleaning	acrylonitrile butadiene styrene (ABS) or polylactic acid (PLA) filaments	GC/MS	GLY, MGLY Benzaldehyde, m-tolualdehyde, 2-oxopentanal	[230,231]
PFBHA	Methanol in Impinger	Freshener's emissions	Terpenes (limonene, terpineol, geraniol) b-ionone (+OH/O3)	GC/MS	GLY, MGLY 4-oxopentanal	[232]

**Table 8.** Instrumentation used in the intercomparison of GLY, MGLY and NO<sub>2</sub> measurements carried out in the atmospheric simulation chambers EUPHORE (Valencia, Spain) and NCAR (Boulder, Colorado, USA). Based on Thalman et al. [238]

<sup>b</sup>G = GLY, M = MGLY, N = NO<sub>2</sub>.

sources (75–90%, 3 $\sigma$ ), and/or techniques that used offline analysis. The main conclusion was that techniques now exist to conduct fast and accurate measurements of GLY at ambient concentrations, and MGLY under simulated conditions. Measuring ambient concentrations of MGLY would be desirable but remains a challenge. Recent work by Michoud et al. [239] have shown that MGLY can be measured using PTR-ToF-MS and shows reasonable agreement with the DNPH-HPLC-UV method.

In most of the reactions generating GLY and MGLY in the indoor environment other dicarbonylic products are also expected some unsaturated, highly photo-labile and short-lived (e.g., butenedial, 4-oxo-2-pentenal), and hence also powerful sources of radicals in several relevant reactions in the indoor environment for which analytical determination could be even more challenging.

## 2.8. Photolysis rates (*J* values)

To accurately determine the role of photolysis processes in indoors atmospheres, it is necessary to characterize both the natural light transmitted through windows as well as light from artificial sources, in terms of wavelength and intensity. Indeed, determining the production rate of radicals or other species by photolysis requires the photolysis rate *J* (in s<sup>-1</sup>) of the species being photolyzed, which is given by:

$$J = \int_{\lambda_{min}}^{\lambda_{max}} F(\lambda) \times \sigma(\lambda) \times \phi(\lambda) d\lambda$$

Here  $F(\lambda)$  is the actinic flux (photons cm<sup>-2</sup> nm<sup>-1</sup> s<sup>-1</sup>),  $\sigma(\lambda)$  is the cross section of the molecule (cm<sup>2</sup>) at the wavelength  $\lambda$  (nm) and  $\phi(\lambda)$  is the dimensionless quantum efficiency, i.e., the probability of photodissociation of the molecule after absorption of a photon at wavelength  $\lambda$ .  $\lambda_{min}$  and  $\lambda_{max}$  represent the range of wavelengths that need to be considered to cover the absorption spectrum of the molecule.  $\sigma(\lambda)$  and  $\phi(\lambda)$  are spectroscopic parameters, which have been measured in the laboratory for many molecules of atmospheric interest, often as a function of pressure and temperature, and are

provided by databases such as the MPI Spectral Atlas ([http://satellite.mpic.de/spectral\\_atlas/index.html](http://satellite.mpic.de/spectral_atlas/index.html)). The production rate of the species generated by photolysis can then be calculated multiplying  $J$  with the concentration of the photolyzed species.

Spectroradiometers are able to measure actinic fluxes as a function of wavelength, which can then be combined with literature data to calculate photolysis frequencies [240]. For the measurement of photolysis rates specifically of  $O_3$  to form  $O(^1D)$ , and  $NO_2$  to form  $O(^3P)$ , fixed bandwidth filter radiometers can be also used [241]. A comprehensive account of the different methods is provided by Hofzumahaus [240]. Some of the different types of spectroradiometers (providing spectrally resolved data) include:

1. LICOR or Ocean optics spectrometer [10,242,243].  
Both instruments have a cosine receptor and measure irradiance. From the irradiance measurement  $I(\lambda)$  at the wavelength  $\lambda$  (in nm), the actinic flux  $F(\lambda)$  is calculated by dividing  $I$  by cosine  $\theta$ ,  $\theta$  being the azimuth angle under conditions of direct sunshine. For conditions of indirect sunlight it is considered that the light comes from all directions (through the window and by reflection off surfaces) and is isotropic, the actinic flux is obtained by multiplying the irradiance by a factor of 2.
2. METCON spectroradiometers [9,244].
3. PAR (photosynthetically active radiation) sensors provide integrated light intensity (400-750 nm). When calibrated by a spectrometer, these sensors can provide an integrated photon flux (irradiance) over the wavelength range 400-750 nm. As PAR sensors are compact and cheap, they can be used to map the light distribution in a room [243].

### 3. Future indoor measurements of radicals and radical precursors

The techniques described above for quantifying the concentrations of radicals and radical precursors illustrate the challenge of measuring highly reactive species. Below we consider the analytical and operational characteristics needed for quantifying indoor air components.

Occupied indoor spaces pose particular measurement challenges, and it may be necessary to adapt instrumentation developed for outdoor measurements to the indoor environment. Instruments must operate in relatively confined indoor spaces that might be occupied by people during the measurements. Instrumentation therefore should be as unobtrusive as possible; this includes considerations of instrumentation size and minimizing the generation of heat and noise (for example, from instrumentation pumps). Emissions of instrument chemicals and exhaust gases must also be considered and minimized.

Indoor concentrations of radicals and their precursors can differ considerably from outdoors. For example, indoor combustion sources like cooking can produce high local HONO levels, and cleaning activities can release much higher levels of chlorinated compounds than would occur outdoors. In studies where episodes of high concentration are the primary focus, this could allow instrumentation sensitivity to be slightly relaxed. In

other cases, instrumentation may need to have a wider dynamic range to handle both low and high concentrations.

The temporal resolution of radical measurements must be sufficiently short to capture changes in the concentrations of reactive species on the timescale of indoor activities such as cooking or cleaning. Real-time measurements with a measurement interval of a few minutes are adequate for many purposes. However, some of the techniques discussed above (such as derivatisation, followed by off-line analysis) have much longer sample acquisition times. Besides the extra effort and time required for off-line analysis, such approaches would be too slow to capture fast changes in indoor air composition and transformation.

The spatial variability of reactive species must also be evaluated. The high reactivity of some radical species and the location of different sources and sinks can produce significant variation in radical concentrations across an indoor space. It would therefore be advisable to compare fast radical measurements with integrated measurements (using for example, OH tracers). Comparative measurements in direct sunlight, and in the shade or dark zones, are needed to characterize and quantify the contribution of reactive chemistry in different locations in an indoor space. Such measurements would help to establish the relative importance of ozonolysis of alkenes versus photolytic sources, for example. The contribution of direct emissions (such as HONO from candles, gas fires, and stoves) is also unclear and could be extremely large; measurements around such sources are needed. This is an important question because the health impacts of combustion sources in confined indoor environments are of special concern, both from direct emissions and through their influence on indoor air chemistry.

In addition to chemical measurements, spatial differences in the actinic flux also influences the spatial variation in the concentrations and chemical processes taking place indoors. The transmission of light to the indoor environment affects HONO photolysis, to produce OH radicals, and other processes, such as chlorine chemistry and photosensitization processes mediated by several household chemicals. The actinic flux is therefore an important parameter in indoor photochemistry and should be measured at difference locations in an indoor space, in parallel with chemical observations. Measurements are also needed in a range of locations and conditions (including types of windows and building orientation) representative of the indoor environment.

Except for the Criegee intermediates and some chlorine species, techniques are now available which are sufficiently sensitive for exploring the contribution of radicals and their precursors to oxidation processes within the indoor environment. Previous studies of these species have already revealed surprises about their role in the indoor environment. However, comprehensive measurements of these species will not be routinely possible because monitoring atmospheric radicals and their precursors requires custom-built, highly specialized, and specific instrumentation. The most important exceptions in this regard are CIMS instruments (which can measure several of the above species, depending on the ionization source) and LOPAP (for HONO measurements). For other species requiring custom instruments, the instruments either have to be developed in-house — a formidable challenge — or measured in collaboration with research groups that possess the necessary instrumentation. In this case, the technique and instrument used will be dictated by instrument (and collaborator) availability. Nevertheless,

understanding indoor air chemistry is an important scientific objective, and some indoor air measurement campaigns will need to combine the instrumentation and collaborations needed to explore atmospheric chemistry in different indoor environments.

Continued improvement of existing techniques for outdoor measurements, and their adaptation for use in occupied indoor spaces, would also be beneficial. Sensitive and accurate measurements remain vital, as does extending measurements to other species of potential interest, like dicarbonylic products besides GLY and MGLY. Large radical campaigns including  $\text{NO}_y$ /VOC/radical/chlorine compound concentrations, actinic flux and the air exchange rate are also recommended.

To date, standardized measurement methods for the assessment of indoor air quality have been mainly based on discontinuous measurements of long-lived trace substances. The presence of short-lived indoor oxidants and their effect on the abundance of oxidation products that building occupants inhale, ingest or dermally absorb is not tackled by the internationally standardized assessment of indoor air quality. Future research efforts and corresponding standardization activities should focus on expanding our current understanding of the conditions and underlying chemistry that produce high concentrations of pollutants indoors.

Finally, complementary measurements of OH reactivity during standardized material emission tests can help to investigate potential uncertainties in material emissions with special regard to standardized test protocols and material labels. Such measurements will help derive estimates for the formation rate of secondary indoor pollutants resulting from OH-initiated oxidation processes.

## Acknowledgements

This publication is based upon work from COST Action CA17136 - Indoor Air Pollution Network (INDAIRPOLLNET) supported by COST (European Cooperation in Science and Technology) ([www.cost.eu](http://www.cost.eu)) for which the authors are grateful. The assistance of Aime Ruus for formatting the manuscript is also warmly thanked.
