Dimethylsulfoniopropionate (DMSP) is a ubiquitous organosulfur compound in marine environments with important functions in both microorganisms and global biogeochemical carbon and sulfur cycling. The SAR11 clade and marine *Roseobacter* group (MRG) represent two major groups of heterotrophic bacteria in Earth's surface oceans, which can accumulate DMSP to high millimolar intracellular concentrations. However, few studies have investigated how SAR11 and MRG bacteria import DMSP. Here, through comparative genomics analyses, genetic manipulations, and biochemical analyses, we identified an ABC (ATP-binding cassette)-type DMSP-specific transporter, DmpXWV, in *Ruegeria pomeroyi* DSS-3, a model strain of the MRG. Mutagenesis suggested that DmpXWV is a key transporter responsible for DMSP uptake in strain DSS-3. DmpX, the substrate binding protein of DmpXWV, had high specificity and binding affinity towards DMSP. Furthermore, the DmpX DMSP-binding mechanism was elucidated from structural analysis. DmpX proteins are prevalent in the numerous cosmopolitan marine bacteria outside the SAR11 clade and the MRG, and *dmpX* transcription was consistently high across Earth's entire global ocean. Therefore, DmpXWV likely enables pelagic marine bacteria to efficiently import DMSP from seawater. This study offers a new understanding of DMSP transport into marine bacteria and provides novel insights into the environmental adaption of marine bacteria.

INTRODUCTION

Approximately eight billion tonnes of the compatible solute dimethylsulfoniopropionate (DMSP) is produced per annum in Earth's surface waters, by marine algae, bacteria, corals, and some plants [1, 2]. While some DMSP is broken down by the DMSP-producers themselves [3, 4], the vast majority of DMSP is released into marine environments where it is utilized by other heterotrophic microorganisms (mainly marine bacteria) as a carbon, energy, and/or sulfur source [2, 5, 6]. Marine bacteria degrade DMSP to volatile dimethyl sulfide (DMS) and/or methanethiol (MeSH), which play important roles in the global sulfur cycling, with potential consequences for global climate regulation [7, 8].

The SAR11 clade and the marine *Roseobacter* group (MRG) represent two major groups of heterotrophic bacteria in surface ocean waters [9–11] and are active participants in marine carbon, sulfur, and nitrogen cycles [12–14]. Their capacity to metabolize a diverse range of organic matter compounds partially explains their success in different marine habitats [10, 15]. DMSP is ubiquitous in marine environments, with its concentration ranging from nanomolar to several micromolar [2]. Both the SAR11 clade and the MRG are able to utilize DMSP as a nutrient [5, 7], most likely as

a source of reduced sulfur, but also of carbon [16]. It has also been reported that intracellular DMSP concentrations can reach 70 mM in the MRG bacterium *Ruegeria pomeroyi* DSS-3 [17], and 180 mM in the SAR11 bacterium *Pelagibacter* HTCC1062 [5], potentially for its antistress properties, as e.g. an osmolyte [2].

DMSP cannot be imported into cells without a specific transporter [18]. To accumulate DMSP to high millimolar intracellular concentrations, efficient transporters are necessary. To date, two transporter families have been reported to import DMSP into cells, the BCCT (betaine, carnitine, and choline transporters) and the ABC (ATP-binding cassette) family [7]. The BCCT transporters are single-subunit transmembrane proteins involved in the uptake of betaine-type organic osmolytes, such as choline and carnitine [19]. DddT, a BCCT transporter whose gene is often found in a cluster with DMSP lyase genes (e.g. *dddD* and *dddX*) in marine DMSP-catabolising bacteria, was reported to import DMSP when heterologously expressed in *Escherichia coli* [20–22]. Other BCCT transporters that imported DMSP and betaine, whose genes were not linked to known DMSP lyase genes, were isolated from the MRG bacteria *Roseovarius nubinhibens* ISM and *Sulfitobacter* sp. EE-36 [21].

ABC transporters, ubiquitous in prokaryotes and eukaryotes, are one of the oldest and largest protein families [23, 24]. In Gram-negative bacteria, they usually consist of three subunits: a periplasmic substrate-binding protein (SBP) responsible for the primary recognition and binding of substrate, a transmembrane domain constituting the translocation pathway, and a cytoplasmic ATP-binding domain to hydrolyse ATP and provide energy for transport. Current knowledge on the ABC transporters which can import DMSP derives mainly from work in *E. coli* and *Bacillus subtilis* [21, 25–27]. For instance, some bacteria, e.g. *Burkholderia ambifaria* AMMD, contain ABC transporter genes in gene clusters with *dddD* and these were also shown to import DMSP in *E. coli* [21]. More recently, physiological experimentation revealed the presence of a high-affinity glycine betaine transporter, likely related to the ABC-type family, capable of importing DMSP in SAR11 bacteria, although the specific identity wasn't established [28].

All known transporters capable of importing DMSP are multi-functional, i.e., they have promiscuous substrate specificity and are not specific for DMSP [21, 25–28]. Yet, cosmopolitan SAR11 and MRG bacteria, which inhabit oligotrophic regions of the ocean, accumulate high intracellular DMSP concentrations [5, 17]. Thus, we hypothesised that there would be a highly efficient and specific DMSP importer yet to be discovered.

Here, we identified an ABC-type DMSP transporter (DmpXWV) from *R. pomeroyi* DSS-3, the best-characterized model MRG strain which was isolated from coastal seawater [29–33], concentrates DMSP to 70 mM and utilizes it as a carbon and sulfur source [7, 31, 34]. DmpX, the SBP of DmpXWV, exhibited a high binding affinity and specificity for DMSP in vitro. Mutagenesis experiments suggested that DmpXWV is a key transporter responsible for DMSP uptake in strain DSS-3. The crystal structure of a DmpX homologue in complex with DMSP was also solved, and the DMSP-binding mechanism of DmpX was predicted. Furthermore, bioinformatic analysis indicated that *dmpX* genes were prevalent in cosmopolitan marine bacteria. This study provides new insights into the environmental adaptation of marine bacteria and provides a better understanding of microbial organosulfur cycling.

MATERIALS AND METHODS

Bacterial strains and growth conditions

Ruegeria pomeroyi DSS-3 was routinely cultivated in the marine broth medium at 30 °C. The *E. coli* strain BL21(DE3) was grown in the Lysogeny Broth (LB) medium at 37 °C.

Construction and complementation of $\Delta dmpXWV$

To create the $\Delta dmpXWV$ knockout mutant regions of homology at the 5' and 3' ends of *dmpXWV* were amplified, alongside the gentamicin cassette from the p34s-Gm plasmid. Amplified DNA fragments were assembled into linearised pk18mobsacB using the HiFi assembly kit (New England Biolabs) according to the manufacturer's instructions. To construct the complementation plasmid, *dmpXWV* was cloned into linearised pBBR1McS-km using the HiFi assembly kit. Plasmids were electroporated into competent *Escherichia coli* S17.1 λ pir and conjugated into *R. pomeroyi* DSS-3. The knockout mutant was selected onto minimal media plates containing gentamicin (10 μ g/ml), with resultant colonies screened for kanamycin resistance. Kanamycin-sensitive clones were PCR screened and products sequenced to confirm a double crossover. The complemented mutant strain was selected on MB plates containing gentamicin (10 μ g/ml) and kanamycin (80 μ g/ml), and colonies confirmed by PCR screening and sequencing.

Gene cloning, point mutation and protein expression and purification

The genes encoding SBPs from *R. pomeroyi* DSS-3 or *R. nubinihibens* ISM were amplified from the genome of *R. pomeroyi* DSS-3 or *R. nubinihibens* ISM by PCR using *FastPfu* DNA polymerase (TransGen Biotech, China). The *dmpX* homologue from *P. sp.* strain HTCC7211 (locus tag HTCC7211_00013840)

was synthesized by the Beijing Genomics Institute (China). The related genes were then cloned into the *NdeI/XhoI* restriction sites of the pET-22b vector (Novagen, Germany) with a C-terminal His tag. Point mutations in DmpX were introduced using the PCR-based method and verified by DNA sequencing. The SBPs and corresponding mutant forms were produced in *E. coli* BL21 (DE3). The cells were cultured in the LB medium with 0.1 mg/ml ampicillin at 37 °C to an OD₆₀₀ of 0.8–1.0 and then induced at 18 °C for 16 h with 0.5 mM isopropyl- β -D-thiogalactopyranoside (IPTG). After induction, cells were collected by centrifugation, resuspended in the lysis buffer (50 mM Tris-HCl, 100 mM NaCl, 0.5% glycerol, pH 8.0), and lysed by a pressure crusher. The proteins were first purified by affinity chromatography on a Ni²⁺-NTA column (GE Healthcare, US), and then fractionated by gel filtration on a Superdex G75 column (GE healthcare, US).

Isothermal titration calorimetry measurements

Isothermal titration calorimetry (ITC) measurements were performed at 25 °C using a MicroCal iTC200 system (GE Healthcare, US) or MicroCal PEAQ-ITC system (Malvern Panalytical, UK). The sample cell was loaded with 280 μ l of protein sample (30–100 μ M), and the reference cell contained distilled water. The syringe was filled with 40 μ l of substrates (100 μ M–1 mM). The proteins and substrates were kept in the same buffer containing 10 mM Tris-HCl (pH 8.0) and 100 mM NaCl.

Crystallization and data collection

The purified *RnDmpX* protein was concentrated to 7 mg/ml in 10 mM Tris-HCl (pH 8.0) and 100 mM NaCl. To obtain crystals of the *RnDmpX*/DMSP complex, *RnDmpX* protein was mixed with DMSP in a 1:5 molar ratio. Initial crystallization trials for the *RnDmpX*/DMSP complex were performed at 20 °C using the sitting-drop vapor diffusion method. Diffraction quality crystals of the *RnDmpX*/DMSP complex were obtained in hanging drops containing 0.2 M magnesium chloride, 0.1 M Bis-Tris (pH 5.5), and 25% (wt/vol) polyethylene glycol 3350 at 20 °C after 2-weeks incubation. Crystals of the *RnDmpX*/DMSP complex soaked with 5-amino-2,4,6-triiodoisophthalic acid (I3C) were obtained by soaking the *RnDmpX*/DMSP complex with I3C compound according to the protocol of the I3C Phasing Kit (Hampton Research, US). Diffraction quality crystals of the *RnDmpX*/DMSP complex were obtained in hanging drops containing 0.2 M calcium chloride, 0.1 M Hepes (pH 7.0), and 20% (wt/vol) polyethylene glycol 6000 at 20 °C after 2-weeks incubation. X-ray diffraction data were collected on the BL19U1 and BL17U1 beamlines at the Shanghai Synchrotron Radiation Facility. The initial diffraction data sets were processed with the HKL3000 program [35].

Structure determination and refinement

The crystals of the *RnDmpX*/DMSP complex and the *RnDmpX*/DMSP complex soaked with I3C belong to the *P*₄1 space group. The structure of the *RnDmpX*/DMSP complex soaked with I3C was determined by single-wavelength anomalous dispersion phasing. The crystal structure of the *RnDmpX*/DMSP complex was determined by molecular replacement using the CCP4 program Phaser [36] with the structure of the *RnDmpX*/DMSP complex soaked with I3C as the search model. The refinements of these structures were performed using Coot [37] and Phenix [38]. All structure figures were processed using the program PyMOL (<http://www.pymol.org/>).

Circular dichroism (CD) spectroscopy

CD spectra for WT *RnDmpX* and its mutants were carried out in a 0.1 cm-path length cell on a JASCO J-810 Spectrometer (Japan). All proteins were adjusted to a final concentration of 30 μ M in 10 mM Tris-HCl (pH 8.0) and 100 mM NaCl. Spectra were recorded from 250 to 200 nm at a scan speed of 200 nm/min.

¹⁴C-DMSP synthesis and determination of radioactive and molar concentration

¹⁴C-DMSP ([1-¹⁴C]DMSP) was synthesised from ¹⁴C-acrylic acid and dimethylsulfide as described earlier [20] and diluted at a 1:10 (vol/vol) ratio with ¹²C-DMSP. Triplicates of 1 μ l ¹⁴C:¹²C-DMSP in 3 ml scintillation fluid (EcoLume Liquid Scintillation Cocktail, MP Biomedical, US) were measured on a liquid scintillation analyzer (Tri-Carb 2800TR, Perkin Elmer, UK) after overnight equilibration. The radioactive concentration of the ¹⁴C-DMSP stock thus was determined to be 0.448 kBq μ l⁻¹.

To confirm the identity and concentration of ¹⁴C:¹²C-DMSP, we used a published LC-MS approach for nitrogen-containing osmolytes quantification [39] due to the structural similarity of the nitrogen-osmolyte glycine

betaine and the sulfur-containing DMSP. The radiolabelled DMSP-stock was diluted 10^6 times in methanol:chloroform: water (12.5:1, vol/vol) and 200 nM d_{11} -glycine betaine (Cambridge Isotope Laboratories Inc., US) added as internal standard (ISTD) to analytical triplicates. Sample separation was performed using a Discovery HS F5 column and HS F5 Supelguard column (both Supelco, US) on a Dionex 3400RS HPLC coupled to an amaZon SL ion trap mass spectrometer (Bruker, UK) for mass detection via Electrospray ionisation in positive ion mode. In parallel, triplicate standards covering a range of 0.005–2 μ M DMSP (dimethylpropiethetin hydrochloride, Supelco) were prepared in methanol:chloroform: water (12.5:1, vol/vol), spiked with 200 nM d_{11} -glycine betaine ISTD and measured by HPLC-MS to obtain a calibration curve [40]. ^{12}C -DMSP was detected at m/z 135 and the ISTD at m/z 129 using Bruker QuantAnalysis software to determine the ratio of the peak area for ^{12}C -DMSP to the ISTD in each sample. The molar concentration of ^{12}C -DMSP in the ^{14}C : ^{12}C -DMSP stock was found to be 328.8 ± 15.2 mM. Since ^{14}C could not be detected, the ratio of ^{14}C : ^{12}C might have been lower than the assumed 1:10 (vol/vol) ratio.

Uptake of ^{14}C -labeled DMSP

A single colony of *R. pomeroyi* DSS-3 WT, Δ *dmpXWV* mutant, or complemented Δ *dmpXWV* mutant was inoculated into 5 ml of marine broth medium (MB) and grown overnight at 30 °C under constant shaking (170 rpm). 1 ml preculture was inoculated into 50 ml MB and grown at 30 °C with shaking (130 rpm) until an OD_{540} of ~0.5–0.7 was reached, then used for DMSP uptake assays.

Due to a relatively low radiochemical and mid-millimolar range molar concentration of the ^{14}C : ^{12}C -DMSP stock, we could not conduct uptake kinetics experiments. Instead, we used three DMSP concentrations (50, 150, and 300 μ M) and added them to 3 ml of cultures in biological triplicates. Cells were incubated at 30 °C with shaking (130 rpm) for 5 min, filtered onto 0.2 μ m pore size Supor filters (\varnothing 25 mm, Pall Corporation, US), and washed 3x with 1 ml MB medium. Wet filters were transferred to 6 ml scintillation vials and 3 ml Ecolume Liquid Scintillation Cocktail added. After equilibration overnight, samples were measured on a Tri-Carb 2800TR liquid scintillation analyzer. Cells fixed in 2% (vol/vol) freshly prepared paraformaldehyde solution for >15 min at 4 °C in the dark prior to radioisotope addition were used for background correction. Uptake rates were normalized by cell number. A Shapiro-Wilk test was used to test for normal distribution of uptake rates and a two-way ANOVA with Tukey's multiple comparison test to analyse whether uptake rates of the wild-type and mutant cultures at the three different DMSP concentrations were significantly different.

Flow cytometry

Bacterial cell numbers used for normalization of uptake rates were determined by flow cytometry [41]. 1 ml culture was fixed with a final concentration of 0.5% (vol/vol) glutaraldehyde (Electron microscopy grade, BDH, AE) for 30 min at 4 °C, snap frozen in liquid nitrogen, and stored at –80 °C. Samples were thawed at 37 °C for 5 min, stained with SYBR gold (Invitrogen, US) (final concentration 10^{-4} of commercial stock) for 10 min at 60 °C in the dark. 75 to 200-fold sample dilutions in sterile TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 8.0) were counted in analytical triplicates on a CytoFLEX flow cytometer (Beckman Coulter, UK) at a flow rate of 30 μ l min^{-1} for 60 sec. The instrument was equipped with a 50 mW 488 nm solid-state diode laser with standard filters and the discriminator set to 525 nm (green fluorescence) (Fig. S1).

Bioinformatic analysis

All phylogenetic reconstructions were performed using IQTREE and tress were edited to determine phylogenetic relationships between *DmpX* and other SBPs encoding the pfam04069 (OpuAC) domain, we used the IMG/JGI database and online bioinformatics server (<https://img.jgi.doe.gov>). Strains ($n=8$) previously shown to possess functionally characterised representatives of this SBP family were searched for any ORFs containing the pfam04069 domain (Function search, 'filter' = pfam[list]), see Table S1 for strains and genes used for Fig. 1. Next, genomes from bacterial isolates, MAGs and SAGs ($n=8730$) related to phylogenetically distinct marine bacteria (cyanobacteria and heterotrophs) and archaea, deposited in IMG/JGI (as of 29th November 2022), were scrutinised for the presence of any ORFs encoding the pfam04069 (OpuAC) domain (Function search, 'filter' = pfam[list]). 8277 ORFs from ~3400 genomes were identified and downloaded. Using a local version of blast+(v2.10.0), these ORFs were screened

Fig. 1 Phylogeny of all identified SBPs containing the pfam04069 domain in selected marine bacteria related to the MRG (strains *Ruegeria pomeroyi* DSS-3; *Roseovarius nubinhibens* ISM) and the SAR11 clade (*Pelagibacter* sp. HTCC7211), as well as selected bacteria including *Escherichia coli* (Ec), *Pseudomonas syringae* (Ps), *Sinorhizobium meliloti* (Sm) that possess experimentally characterised SBPs with affinity for closely related DMSP analogue. These include TMAO-TmoX, choline-ChoX, carnitine-CaiX, proline betaine-ProX, glycine betaine-BetX, and histidine-HisX.

by BLASTP (stringency e^{-50} ; minimum similarity 30%) using strain DSS-3 as the query sequence, returning 1427 ORFs (Table S2). A phylogenetic tree was reconstructed, using TmoX as the outgroup. Any sequences clustering outside the *DmpX* major clade were removed from the data. Using HMMER v3.3 (hmmbuild), we generated a manually curated profile hidden Markov model (pHMM) using sequences falling within the *DmpX* clade and possessing all key residues. Based on our previous research [13, 42], we also generated a pHMM for TmoX, a highly synthesised SBP in the ocean [13].

The Tara Oceans metagenomes (OM_RGC_v2_metaG) and metatranscriptomes (OM_RGC_v2_metaT) were searched using these pHMMs according to a published method [43]. Briefly, the Ocean Gene Atlas web interface [44] was used to extract sequences and abundances, using a stringency of e^{-70} . Sequence abundances were normalized using the median abundance of 10 single-copy marker genes [45], each with a stringency of e^{-40} , in both metagenomes and metatranscriptomes. Normalized abundances per site were summed by phylogeny at the level of Order, if available, and by the lowest available taxonomic rank above that if not available.

RESULTS

Identification of a potential DMSP specific ABC transporter

R. pomeroyi DSS-3 was used as the model to identify the presence of ABC transporters involved in DMSP uptake since this bacterium is well known to grow on DMSP and it accumulates DMSP at 70 mM intracellular levels [17, 31]. We first screened the *R. pomeroyi* DSS-3 genome for genes encoding SBPs containing a pfam04069 domain. This substrate binding domain is found in a number of characterized SBPs that are able to transport DMSP and other related molecules, such as glycine betaine, choline, carnitine and trimethylamine *N*-oxide (TMAO) [13, 46]. This analysis identified four open reading frames (SPO1131, SPO1548, SPO2441 and SPOA0231) encoding SBPs (Fig. 1), including the previously characterized TMAO-specific SBP, TmoX (encoded by SPO1548) that does not show any binding affinity to DMSP [13, 42], and the SPOA0231 that had ~70 % amino acid identity to a gene product from *Rhodobacteriales* bacterium KLH11, whose gene is in a gene cluster with *dddD* [21].

To verify whether the other three ORFs encoding SBPs (i.e. SPO1131, SPO2441 and SPOA0231) could bind DMSP, we over-expressed them in *E. coli*, purified the recombinant proteins, and measured their affinities for DMSP using isothermal titration

Fig. 2 Characterization of the DmpX protein and the genomic position of *dmpXWV*. **a** ITC data for titrations of DMSP into recombinant DmpX from *R. pomeroyi* DSS-3. **b** The DMSP transporter gene cluster in the genome of *R. pomeroyi* DSS-3. **c** ITC data for titrations of DMSP into recombinant DmpX from *Pelagibacter* sp. HTCC7211. **d** The DMSP transporter gene cluster in the genome of *Pelagibacter* sp. HTCC7211.

calorimetry (ITC). The recombinant SBP, encoded by SPO2441, possessed a high binding affinity for DMSP, with a K_d (dissociation constant) of 1.1 μM (Fig. 2a), while the other two recombinant SBPs (encoded by SPO1131 and SPOA0231) did not. Hereafter we designate the SBP encoded by SPO2441 as DmpX, with Dmp standing for Dimethylsulfoniopropionate. To analyse the substrate specificity of DmpX, we tested the affinities of this SBP for DMSP analogues, including TMAO, betaine, choline, and carnitine using ITC. Compared to DMSP, DmpX presented little binding affinity for TMAO, betaine, choline, and carnitine (Table S3), suggesting that DmpX is highly specific for DMSP.

In the *R. pomeroyi* DSS-3 genome, *dmpX* is located in a gene cluster next to ORFs encoding a transmembrane subunit (SPO2442) and an ATP-binding subunit (SPO2443) of the ABC transporter (Fig. 2b). Usually, the SBP confers the substrate specificity of the ABC transporter [13, 46], which suggests that SPO2441-2443 encode a transporter specific for DMSP. Hereafter we designate SPO2441-2443 as genes encoding DmpX, DmpW, and DmpV, respectively. It is noteworthy that a DmpX-like protein is coded for in the genome of SAR11 strain *Pelagibacter* sp. HTCC7211 (WP_034399263.1), which shared ~35% amino acid identity with *R. pomeroyi* DSS-3 DmpX. To determine whether this SAR11 SBP (hereafter designated DmpX⁷²¹¹) is also capable of binding to DMSP, we chemically synthesized the gene, over-produced the recombinant SBP in *E. coli*, and purified it prior to ITC titration. DmpX⁷²¹¹ also had a high binding affinity for DMSP,

with a K_d of 100 nM (Fig. 2c, d). Together, our data suggest that these model MRG and SAR11 clade bacteria encode a high-affinity ABC transporter for DMSP uptake.

The importance of *R. pomeroyi* DSS-3 DmpXWV in the import of DMSP

To verify the function of *dmpXWV* in vivo, a $\Delta dmpXWV::Gm$ mutant was constructed, which disrupted the genes encoding the entire *dmpXWV* gene cluster. To uncover the role of *dmpX* in DMSP transport, we performed a ¹⁴C-radioisotope uptake experiment using ¹⁴C-DMSP and compared ¹⁴C- uptake at three concentrations (50, 150, and 300 μM). Uptake of ¹⁴C-DMSP in the mutant $\Delta dmpXWV::Gm$ significantly decreased in comparison to the wild-type (WT) ($p < 0.001$) with the strongest reduction at 50 μM (~5 times) and the lowest decrease at 300 μM (~3 times) (Fig. 3, Table S4). Complementation with the *R. pomeroyi* *dmpXWV* gene did partly restore ¹⁴C-DMSP import (Fig. 3). These uptake patterns support that *dmpXWV* is a DMSP transporter although it is clear that other DMSP transporters also exist in this bacterium.

The crystal structure and DMSP-binding mechanism of DmpX

To study the DMSP-binding mechanism of DmpX, we attempted to solve the crystal structure of DmpX in the presence and absence of DMSP. While DmpX proteins of *R. pomeroyi* DSS-3 and *Pelagibacter* sp. HTCC7211 did not yield crystals, a DmpX homologue from MRG strain *Roseovarius nubinhibens* ISM,

Fig. 3 DmpXWV is important for the uptake of DMSP in *R. pomeroyi* DSS-3. ¹⁴C-DMSP uptake in the WT, $\Delta dmpXWV::Gm$ mutant, and complemented mutant (comp. $\Delta dmpXWV::Gm$) at three concentrations by spiking DMSP in the marine broth medium. The error bar represents the standard deviation of triplicate experiments. Small letters indicate significant differences ($p < 0.05$) between wild-type, mutant and complemented mutant cultures at different DMSP concentrations based on a two-way ANOVA with Tukey's multiple comparison test.

RnDmpX, sharing 58% amino acid identity with *R. pomeroyi* DSS-3 DmpX, yielded good quality crystals when co-crystallization with DMSP was conducted. The recombinant *RnDmpX* also presented a high binding affinity for DMSP, with a K_d of 474 nM (Fig. S2), and the crystal structure of *RnDmpX* in complex with DMSP was solved (Table S5). *RnDmpX* comprises two domains connected by two hinge regions (Val106-Gly111 and Arg244-Val247), with a DMSP molecule bound between the two domains (Fig. 4a).

The binding pocket of *RnDmpX* is composed of Trp35, Thr64 and Trp84 from domain I, and Glu113, Trp152, Ala153, Tyr200 and Trp202 from domain II (Fig. 4b). Residues Thr64 and Ala153 participate in binding DMSP through hydrogen bonds with the carboxyl group of DMSP (Fig. 4b). Glu113 also participates in binding DMSP through a water-mediated hydrogen bond with DMSP (Fig. 4b). The side chains of the four tryptophan residues form a hydrophobic cage to accommodate the tertiary sulfonium group of DMSP (Fig. 4b). In particular, we found that Tyr200 could form a hydrogen bond with the positive-charged sulfur of DMSP (Fig. 4c). The DMSP binding mode of *RnDmpX* shares similarities with those reported in DMSP lyases [47, 48]. However, to the best of our knowledge, the hydrogen bond interaction between residues and the sulfur atom of DMSP has not been reported before. When Tyr200 was mutated to Ala or Phe, the binding affinities of *RnDmpX* for DMSP were abolished (Fig. S3), suggesting that this interaction plays an important role in DMSP binding. Circular-dichroism (CD) spectroscopy analysis showed that the secondary structures of the mutants exhibit little deviation from that of WT *RnDmpX* (Fig. S4), indicating that binding affinity loss was caused by amino acid replacement rather than by structural change. Residues involved in binding DMSP are highly conserved in MRG and SAR11 clade (Fig. S5), suggesting that the binding mechanism of DmpX in these marine bacteria may be similar to that in *R. nubinhibens* ISM.

Distribution of DmpXWV in marine bacteria through comparative genomics and metagenomics/metatranscriptomics

To determine how widespread and potentially important *dmpXWV* is in marine bacteria, we scrutinised the genomes of both cultivated isolates, metagenome-assembled genomes (MAGs) and single-amplified genomes (SAGs) associated with the marine environment. Using the IMG/JGI database, genomes were scrutinised for the presence of *dmpX* and a phylogenetic tree of the gene products was reconstructed using TmoX, the SBP for TMAO, as the outgroup [13]. We found an unexpected diversity

Fig. 4 Structural analysis of the *RnDmpX*/DMSP complex. **a** Overall structure of the *RnDmpX*/DMSP complex. Domain I is coloured in pink, and domain II in wheat. The location of the DMSP molecule is indicated by a black arrow. **b** Residues composing the DMSP-binding pocket. The oxygen, nitrogen and sulfur atoms in the structure are coloured in red, blue and yellow, respectively. The carbon atoms of residues from domain I are shown in pink, and from domain II in wheat. The carbon atoms of the DMSP molecule are shown in cyan. **c** Structural analysis of the function of residue Tyr200 (carbon atoms coloured in purple) in binding DMSP.

and occurrence of DmpX, revealing vast expansion outside the MRG and SAR11 clade (Fig. 5). This included occurrence in other abundant *Alphaproteobacteria* (SAR116, unclassified), *Gammaproteobacteria* (*Candidatus* Thioglobus, *Oceanospirillales*), and *Deltaproteobacteria* (SAR324). As seen with other abundant SBPs identified in the ocean, such as TmoX [13] and AepX [43], two distinct polyphyletic clades were apparent, which is predominantly partitioned by lifestyle (free-living versus particle-associated). *RnDmpX* and those from clade I (including DmpX⁷²¹¹) and clade II (including DSS-3) all shared conserved key residues, suggesting a common mechanism was evident across the diversity of DmpX.

Based on this unexpected diversity, we investigated the abundance and phylogeny of *dmpX* in the global ocean metagenomes and metatranscriptomes. We searched the *Tara* Oceans metagenomic and metatranscriptomics datasets for

Fig. 5 Environmental distribution and expression of *dmpX* in the global ocean. Phylogenetic reconstruction of DmpX based on sequences retrieved from genomes of bacterial isolates, MAGs and SAGs. Blue and Red circles represent *Roseobacter* and SAR11 DmpX homologues, respectively, that were experimentally validated in this study or those shown in figure S5.

homologues, using manually curated profile hidden Markov models (pHMMs). Homologous sequences retrieved from our searches were manually examined to ensure essential residues were conserved, and to determine whether DmpX and closely related SBPs i.e. TmoX, could be easily distinguished (Fig. 5). Normalized read abundances were combined with phylogenetic assignments to determine the prevalence of *dmpX* at surface water sampling sites (Fig. 6). The majority of marine *dmpX* genes and transcripts were closely related to *Pelagibacterales*, with unclassified *Alphaproteobacteria* being the next most abundant group. However, sequences belonging to *Rhodobacterales* as well as the gammaproteobacterium *Candidatus Thioglobus* were abundant at sampling sites in the polar oceans (Fig. 6). In certain oceanic regions the relative abundance of *dmpX* transcripts was

significantly higher (*dmpX* copies were up to 700% of median single-copy core gene transcript levels) than its corresponding gene abundance (up to 25% of cells contained *dmpX*), suggesting either DMSP catabolism is disproportionately higher in certain regions, or there are other as yet unidentified transporters active.

DISCUSSION

The microbial use of DMSP as osmolyte or nutrient via DMSP catabolism, are globally important biogeochemical processes [7]. Critically, these processes require the import of DMSP into cells in the heterotrophic and/or phototrophic organisms that do not make DMSP themselves [2, 49]. The MRG and SAR11 clade, two dominant groups in marine surface waters, are key DMSP

Fig. 6 The distribution, diversity, and expression of *dmpX* across the global ocean. *dmpX* gene (a) and transcript (b) abundance by taxonomic assignment in marine surface waters. Normalized gene and transcript abundance in the Tara Ocean dataset (surface water sites only). Circle radius represents normalized abundance, calculated as a percentage of the median gene abundance or transcript abundance of 10 single-copy marker genes. Relative abundance of different taxa at each site is shown as pie charts, summing taxonomy at the level of Order, or the lowest taxonomic rank above Order. In the figure legend, unclassified is abbreviated to Unc., for clarity of presentation.

catabolic bacteria, and thus important drivers of marine carbon and sulfur cycling [5, 7, 17]. However, the importance of these two groups using DMSP as a carbon source was recently questioned [16]. Here, bioinformatics was used to identify ABC transporters with the potential to import DMSP from the genome of the model MRG bacterium *R. pomeroyi* DSS-3. Of four candidate transporters only one, termed DmpXWV, had high binding affinity and specificity for DMSP and this played a key role in DMSP import in *R. pomeroyi* DSS-3 – with a *dmpXWV* mutant significantly losing DMSP import activity compared to wild type strains (Fig. 3). Other potential transporters in *R. pomeroyi* DSS-3, e.g. a DddT-like protein (SPO3186), bioinformatically predicted are likely responsible for the low level DMSP import seen in the *dmpXWV* mutant (Fig. 3).

All the previously reported transporters capable of importing DMSP are likely multifunctional [21, 25–28]. In addition to DMSP, they also imported varied quaternary ammonium compounds (QACs), such as betaine, carnitine, and choline [21, 25–28]. This may be advantageous allowing them to multitask and import varied osmolytes/nutrients when they become available in oligotrophic and or changing settings. However, given that DMSP is ubiquitous in marine environments where sulfur is abundant whilst nitrogen is generally more scarce [28], one would predict the capacity to import DMSP is likely very important for marine bacteria and, thus, such organisms would require a specific DMSP importer. Indeed, biochemical data here suggests that DmpX is one such highly specific DMSP importer found in diverse marine bacteria. Note, we cannot exclude that DmpXWV does not import other compounds structurally related to DMSP into cells in vivo and growth experiments of the *dmpXWV* deletion mutant on a wider range of DMSP analogues would help to provide further

insights. However, our biophysical data presented here demonstrates that the DmpX homologues tested here cannot bind other substrates at environmentally relevant concentrations.

Within many bacteria that cleave DMSP and grow on its catabolites as a source of carbon, their DMSP lyase genes *dddD* or *dddX* are often linked with a transporter gene, either *dddT* or an ABC transporter gene cluster [16, 21, 22]. However, most other DMSP lyase and catabolic genes involved in the demethylation pathway genes are not commonly located in a gene cluster with potential DMSP transporters. The genes encoding DmpXWV identified here are also not colocalised with other known DMSP catabolic genes (Fig. 2b). Bioinformatic analysis revealed *dmpXWV* was prevalent in abundant marine bacteria, including the MRG and the SAR11 clade but also found in cosmopolitan *Gamma*- and *Deltaproteobacteria*. Furthermore, high transcript levels of *dmpX* were detected across the global ocean, with certain oceanic regions exhibiting exceptionally high levels. This further exemplifies the importance of DMSP and its import as a nutrient and antistress compound for marine bacteria.

DMSP shares structural similarities with QACs. The DMSP binding mode of DmpX is similar with the reported binding modes of SBPs for QACs [42, 50–53], which can be summarized as an aromatic box formed by three or four aromatic residues to accommodate the quaternary amine, as well as two or three hydrophilic residues that form hydrogen bonds with the polar atoms of QACs [42, 50–53]. QACs contain a positive-charged nitrogen atom, similar to the positive-charged sulfur atom in DMSP. However, to the best of our knowledge, a hydrogen bond interaction between residues and the nitrogen atom of QACs have never been reported before. Thus, the hydrogen bond formed between Tyr200 and DMSP may represent a novel substrate binding and recognition pattern of SBPs.

To conclude, DMSP is an abundant organosulfur compound in the ocean, and plays important roles in marine stress responses, microbial food webs and the global sulfur and carbon cycling. Despite some bacteria producing DMSP themselves [4, 54–56], the uptake of DMSP is the prerequisite for most marine bacterial utilisation. Here, we identified an efficient ABC-type transporter DmpXWV, which is specific for DMSP and prevalent in numerous cosmopolitan marine bacteria. The DMSP-binding mode of DMSP in DmpX was also revealed. The results offer a better understanding of the global sulfur cycle driven by bacteria.

DATA AVAILABILITY

The structure of *RnDmpX*/DMSP complex has been deposited in the PDB under the accession codes 7YLE.

ACKNOWLEDGEMENTS

We thank the staff from BL19U1 & BL17U1 beamlines of the National Facility for Protein Sciences Shanghai (NFPS) and Shanghai Synchrotron Radiation Facility for assistance during data collection. We thank Jing Zhu from the State Key Laboratory of Microbial Technology of Shandong University for their help in ITC experiments.

AUTHOR CONTRIBUTIONS

C-YL, YC, and Y-ZZ conceived the project and designed the experiments. C-YL and NZ performed protein purification, ITC measurements, structural determination, and gene knockout experiments. MAM performed the ¹⁴C-radioisotope uptake experiment and helped with gene knockout experiments. AM performed bioinformatics analysis. X-LC, S-YW, and CG helped with protein purifications and data analysis. MMA-F and ES assisted with gene knockout experiments. IDEAL and H-HF helped with bioinformatics analysis. C-YL wrote the manuscript. JDT, YC, and Y-ZZ revised the manuscript.
