On the influence of a translating inner core in models of outer core convection

C. J. Davies^{a,*}, L. Silva^a, J. Mound^a

^a*School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK*

Abstract

It has recently been proposed that the hemispheric seismic structure of the inner core can be explained by a self-sustained rigid-body translation of the inner core material, resulting in melting of the solid at the leading face and a compensating crystallisation at the trailing face. This process induces a hemispherical variation in the release of light elements and latent heat at the inner-core boundary, the two main sources of thermochemical buoyancy thought to drive convection in the outer core. However, the effect of a translating inner core on outer core convection is presently unknown. In this paper we model convection in the outer core using a nonmagnetic Boussinesq fluid in a rotating spherical shell driven by purely thermal buoyancy, incorporating the effect of a translating inner core by a time-independent spherical harmonic degree and order 1 (Y_1^1) pattern of heat-flux imposed at the inner boundary. The analysis considers Rayleigh numbers up to 10 times the critical value for onset of nonmagnetic convection, a parameter regime where the effects of the inhomogeneous boundary condition are expected to be most pronounced, and focuses on varying q^* , the amplitude of the imposed boundary anomalies. The presence of inner boundary anomalies significantly affects the behaviour of the model system. Increasing q^* leads to flow patterns dominated by azimuthal jets that span large regions of the shell where radial motion is significantly inhibited. Vigorous convection becomes increasingly confined to isolated regions as q^* increases; these regions do not drift and always occur in the hemisphere subjected to a higher than average boundary heat-flux. Effects of the inner boundary anomalies are visible at the outer boundary in all models considered. At low q^* the expression of inner boundary effects at the core surface is a difference in the flow amplitude between the two hemispheres. As q^* increases the spiralling azimuthal jets driven from the inner boundary are clearly visible at the outer boundary. Finally, our results suggest that, when the system is heated from below, a Y_1^1 heat-flux pattern imposed on the inner boundary has a greater overall influence on the spatio-temporal behaviour of the flow than the same pattern imposed at the outer boundary.

Keywords: Inner core translation, outer core convection, zonal flows, inhomogeneous heat-flux

1. Introduction

Free thermal convection of the inner core, driven by either radiogenic heating (Jeanloz and Wenk, 1988) or secular cooling (Buffett, 2009), has been proposed to explain the observed cylindrical anisotropy in inner core P-wave velocity (Morelli et al., 1986; Woodhouse et al., 1986). For this proposition to be viable the inner core must be (at least partially) unstably stratified. Such a stratification may arise if the inner core temperature gradient exceeds the adiabatic gradient at the relevant pressure-temperature conditions; previous models suggest this may be true at present and was more likely in the past (Buffett, 2009; Deguen and Cardin, 2009, 2011). Recent work suggests that the thermal conductivity of the outer core is significantly higher than previously thought (Pozzo et al., 2012; de Koker et al., 2012), which may affect the viability of thermal inner core convection, although these calculations pertain to the liquid phase only. Another possibility is that the inner core is compositionally unstable, which may arise if the amount of light element that remains in the solid on freezing decreases with time (Deguen and Cardin, 2011; Alboussière and Deguen, 2012). In reality the net inner core density gradient is determined by a combination of thermal and chemical effects. Uncertainties in key parameters such the cooling rate at the inner core boundary (ICB), the core-mantle boundary (CMB) heat-flux, and the partition coefficients of the various light elements in the core prevent an unequivocal determination of the inner core stratification and so inner core convection remains a realistic possibility. If the inner core does convect the preferred model likely depends on the bulk viscosity (Deguen and Cardin, 2011). If the viscosity is sufficiently large the inner core could undergo a translational mode of convection involving an eastward drift of inner core material (Monnereau et al., 2010; Alboussière et al., 2010). This mode has been used to explain an observed asymmetry in seismic velocities between eastern and western hemispheres (Tanaka and Hamaguchi, 1997; Niu and Wen, 2001; Waszek et al., 2011) and the existence of a seismically slow layer in the bottom ~ 150 km of the outer core (Souriau and Poupinet, 1991; Kennett et al., 1995; Zou et al., 2008).

Convection in the outer core is driven by a combination of thermal and chemical buoyancy forces that in turn result from the Earth's slow cooling (e.g. Buffett et al., 1996; Gubbins et al., 2003, 2004). These buoyancy forces are likely to be strongest near the base of the outer core (Davies and Gubbins, 2011) where inner core growth due to freezing of the liquid iron alloy releases latent heat (Verhoogen, 1961), and a light component of the outer core mixture, probably oxygen (Alfè et al., 1999), remains in the liquid to provide a source of compositional buoyancy (Braginsky, 1963). Models of outer core convection usually assume that light element and latent heat release at the ICB are spherically symmetric and that convection is driven uniformly from below (e.g. Braginsky and Roberts, 1995; Anufriev et al., 2005); however, the translational mode of inner core convection requires freezing in the western hemisphere and melting in the eastern hemisphere (Monnereau et al., 2010; Alboussière et al., 2010). The asymmetry arises because the eastward drift of inner core material induces a west to east density gradient with heavy material on the freezing western side; hydrostatic adjustment shifts the centre of mass of the inner core eastward so that the eastern part of the inner core is above the melting temperature, leading to localised melting

(Alboussière et al., 2010). Outer core convection is then driven non-uniformly from below: in the western hemisphere, release of latent heat and light elements create outward buoyancy fluxes that drive convection; in the eastern hemisphere, latent heat is absorbed and no light elements are released, thereby creating a negative buoyancy flux.

In this paper we investigate the possible influence of a translating inner core on outer core convection using a simple model of a rotating fluid-filled spherical shell. To incorporate hemispherical variations induced by a translating inner core we note that the turnover time of outer core convection, $\tau_c = d/U \sim 10^2$ yrs (Gubbins, 2007), is much shorter than both the turnover time of the translational mode, $\tau_{ic} = l/v_t \sim 10^8$ yrs, and the timescale for inner core growth $\tau_g = l/v_g \sim 10^9$ yrs (Labrosse et al., 2001). Here d is the outer core shell thickness, U a characteristic outer core velocity, l the inner core radius, $v_t \sim 10^{-10}$ m s⁻¹ (Alboussière et al., 2010) a characteristic translational velocity and $v_g \sim 10^{-11}$ m s⁻¹ a characteristic inner core growth rate. We therefore assume that, on the timescales associated with outer core convection, both the ICB and the thermochemical anomalies resulting from translation are stationary and can be modelled as a time-independent bottom boundary condition in the outer core convection simulation. We further assume that this boundary condition takes the form of a fixed flux. The outer core is well-mixed on timescales associated with inner core convection, implying that the latter should be modelled with an isothermal and chemically homogeneous ICB. Outer core convection must then respond to lateral variations in thermal and chemical fluxes at the ICB induced by the translating inner core. The bottom boundary condition is specified by the pattern and amplitude of thermochemical flux.

In this paper we approximate the pattern of hemispherical melting and freezing by a Y_1^1 spherical harmonic. The amplitude of the anomaly is measured by q^* , the ratio of the peak-to-peak variation and the average flux through the boundary (see §2 for the mathematical definition). Estimates of q^* for the Earth are highly uncertain. The thermal contribution depends on physical properties of the inner and outer cores, some of which are known to within a factor of 3 at the relevant pressure-temperature conditions (Stacey, 2007), and gross quantities such as the CMB heat-flux, which can only be estimated to within a factor of 3–4 at present (Lay et al., 2009) and vary significantly over time (e.g. Nimmo et al., 2004; Nimmo, 2007). The chemical contribution depends on the relative abundance of light elements in both cores (i.e. on the part of the ICB density jump not due to the phase change) and on mixing properties of the core alloy, which are likely to be non-ideal (Helfrich, 2012) and exhibit complex dependencies on partition coefficients (Alboussière et al., 2010; Deguen and Cardin, 2011).

A simple estimate of q^* , q_e^* , can be obtained by neglecting chemical effects and assuming that the only thermal buoyancy source at the ICB is latent heat (thus neglecting secular cooling and the effect of the adiabat, both of which are likely to be smaller than the latent heat (Davies and Gubbins, 2011)). The average ICB heat-flux per unit area, q_L , is then (Gubbins et al., 2003)

$$q_L = \rho_i L \frac{dr_i}{dt} = \rho_i L v_g, \quad (1)$$

where r_i is the ICB radius, ρ_i the inner core density, and L the latent heat. An expression for the maximum heat-flux is obtained by replacing v_g with the translation velocity, v_t , in

84 (1). Assuming that the absolute value of the maximum and minimum heat-flux anomaly
 85 are equal gives the estimate

$$q_e^* = \frac{2v_t}{v_g}. \quad (2)$$

86 Using values from Alboussière et al. (2010) gives present-day estimates in the range $1 \lesssim q_e^* \lesssim$
 87 30 for a CMB heat-flux ranging from 8–11 TW. We vary q^* in our simulations to exhibit
 88 the dependence of the convection on this parameter.

89 This paper is organised as follows. In §2 we describe the numerical model used to
 90 simulate convection in the outer core. In §3.1 we present models with a laterally-varying
 91 Y_1^1 inner boundary condition and a spherically symmetric outer boundary condition. We
 92 discuss the changes in spatio-temporal behaviour that emerge as q^* is varied and conduct a
 93 detailed analysis of the mechanisms that drive large-scale flows in our models. In §3.2 we
 94 briefly discuss models with a laterally-varying Y_1^1 outer boundary condition and a spherically
 95 symmetric inner boundary condition and compare to the results obtained in §3.1. Discussion
 96 and conclusions are presented in §4.

97 2. Methods

98 We consider a model of convection in a rotating spherical shell that incorporates lateral
 99 variations in the thermodynamic boundary conditions. A Boussinesq fluid of constant ther-
 100 mal diffusivity, κ , constant coefficient of thermal expansion, α , and constant viscosity, ν , is
 101 confined to a rotating spherical shell of thickness $d = r_o - r_i$. Here r_i and r_o are respectively
 102 the inner and outer boundary radii in spherical polar coordinates, (r, θ, ϕ) . The fluid rotates
 103 about the axial \mathbf{z} -axis with angular velocity Ω . To relate our results to previous studies and
 104 to avoid double diffusive effects, which we regard as an unnecessary complication at this
 105 stage, we consider a chemically homogeneous system heated from below, the analogue of
 106 outer core convection driven by latent heat release at the inner boundary with no composi-
 107 tional buoyancy. With no flow, the basic steady state temperature, T_0 , is maintained such
 108 that $\nabla T_0 = -(\beta/r^2)\hat{\mathbf{r}}$, where β measures the amplitude of the basic state radial temperature
 109 gradient, \mathbf{r} is the radial position vector and a hat denotes a unit vector. The total tempera-
 110 ture field $T = T_0 + T'$, where T' is the deviation from the basic state temperature. Scaling
 111 length by the shell thickness, d , time by the thermal diffusion time, d^2/κ , and temperature
 112 by β/d , the nondimensional perturbation equations are

$$\frac{E}{Pr} \left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} \right) + \mathbf{z} \times \mathbf{u} = -\nabla \bar{P} + Ra T' \mathbf{r} + E \nabla^2 \mathbf{u}, \quad (3)$$

$$\frac{\partial T'}{\partial t} + (\mathbf{u} \cdot \nabla) T' = \nabla^2 T' + \mathbf{u} \cdot (\beta r^{-2}) \hat{\mathbf{r}}, \quad (4)$$

$$\nabla \cdot \mathbf{u} = 0. \quad (5)$$

113 The pressure gradient $\nabla \bar{P}$, is removed from the problem by taking the curl of (3). The
 114 Ekman number E , Prandtl number Pr , and modified Rayleigh number Ra are

$$E = \frac{\nu}{2\Omega d^2}, \quad Pr = \frac{\nu}{\kappa}, \quad Ra = \frac{\alpha g \beta}{2\Omega \kappa}, \quad (6)$$

115 where g is the gravitational acceleration at the outer boundary. Gravity varies linearly with
 116 radius. The radius ratio, r_i/r_o , of the shell is set to 0.35.

117 The fluid velocity \mathbf{u} is decomposed into toroidal and poloidal components,

$$\mathbf{u} = \nabla \times \mathcal{T} \mathbf{r} + \nabla \times \nabla \times \mathcal{P} \mathbf{r}. \quad (7)$$

118 The toroidal, \mathcal{T} , and poloidal, \mathcal{P} , scalars along with the temperature T' are expanded in
 119 spherical harmonics $Y_l^m(\theta, \phi)$. The radial dependence of all variables is computed using
 120 finite differences.

121 We use no-slip and impenetrable inner and outer boundaries, requiring

$$\mathbf{u}(r_i) = \mathbf{u}(r_o) = 0. \quad (8)$$

122 We also fix the heat-flux on both boundaries. Lateral variations in heat-flux on the inner
 123 boundary (IB) and outer boundary (OB) are modelled using the method described in (Gib-
 124 bons et al., 2007). In all models the pattern of the boundary variation is a Y_1^1 spherical
 125 harmonic. The amplitude of the anomalies is measured by the parameter q^* , defined as
 126 the ratio of the peak-to-peak variation in boundary heat-flux and the average boundary
 127 heat-flux

$$q^* = \frac{q_{max} - q_{min}}{q_0} = \frac{2q_{max}}{q_0}, \quad (9)$$

128 where q_{max} and q_{min} are the maximum and minimal values of the boundary anomaly. q_0 is a
 129 nondimensional measure of the average boundary heat-flux per unit area, $q_0 = (1/r^2)$, and
 130 is approximately a factor of 8 larger at the IB than at the OB. Hence, to impose the same
 131 value of q_{max} at the IB and OB requires that the value of q^* is 8 times larger in the variable
 132 OB heat-flux calculation compared to the variable IB heat-flux calculation.

133 The governing equations (3)–(5) are solved using a pseudo-spectral method. Detailed
 134 descriptions of the code are given in Willis et al. (2007) and Davies et al. (2011).

135 3. Results

136 Table 1 lists all simulations conducted for this work. In order to facilitate comparisons
 137 and to elucidate the effect of the laterally-varying IB condition, we fix the values of E and Pr
 138 and vary Ra and q^* . For simplicity we use the value $Pr = 1$ throughout. The Ekman number
 139 is the major computational challenge. The lowest value of E used in a numerical simulation
 140 is $\sim 5 \times 10^{-7}$ (Kageyama et al., 2008); very few models have been conducted in this parameter
 141 regime, which is still many orders of magnitude higher than the value $E \sim 10^{-15}$ appropriate
 142 to Earth’s outer core. We fix $E = 10^{-5}$, which is low enough for rotation to dominate in
 143 our calculations but high enough to conduct a suite of simulations run for long enough
 144 to obtain time-averages that span many time units. At this value of E a linear stability
 145 analysis (see Gibbons et al. (2007) and Davies et al. (2009) for details) with our chosen
 146 boundary conditions and value of Pr shows that the most unstable azimuthal wavenumber,
 147 $m_c = 9$, and the corresponding value of the critical Rayleigh number, $Ra_c = 25.5$, for the
 148 onset of non-magnetic convection with homogeneous boundaries ($q^* = 0$). We focus on the

149 parameter range $3Ra_c \leq Ra \leq 10Ra_c$, where we expect the influence of the inhomogeneous
 150 boundary condition to be most pronounced. If boundary effects are not important in this
 151 regime we would anticipate that they be less significant in the core where Ra is likely to be
 152 many times supercritical (Gubbins, 2001; Davies and Gubbins, 2011).

153 All simulations were started from the same initial condition with $\mathbf{u} = 0$ and arbitrary
 154 three dimensional seed perturbations superimposed on the basic state temperature profile.
 155 The spatial resolution required to achieve a given level of spectral convergence increases with
 156 Ra . At the lowest values of Ra we found that $N_{max} = 90$ radial points and maximum har-
 157 monic degree $L_{max} = 84$ produced a drop of four orders of magnitude between wavenumbers
 158 with highest and lowest energy. At the highest values of Ra , $N_{max} = 120$ and $L_{max} = 128$
 159 were required to obtain the same convergence.

160 For the subsequent discussion we define the dimensionless kinetic energy $K = K_{\mathcal{T}} + K_{\mathcal{P}}$,
 161 where the toroidal and poloidal components are given respectively by

$$K_{\mathcal{T}} = \frac{1}{2} \langle |\nabla \times \mathcal{T}\mathbf{r}|^2 \rangle,$$

$$K_{\mathcal{P}} = \frac{1}{2} \langle |\nabla \times \nabla \times \mathcal{P}\mathbf{r}|^2 \rangle,$$

162 and angled brackets indicate a time average over the length of the run quoted in Table 1.
 163 The zonal part of the toroidal energy, $K_{\mathcal{T}}^z$, is obtained by retaining only the $m = 0$ harmonic
 164 coefficient.

165 Our choice of nondimensionalisation means that the Péclet number, $Pe = Ud/\kappa =$
 166 $\sqrt{2K/V_s}$, where V_s is the volume of the spherical shell, measures the amplitude of the
 167 velocity U . With all other parameters fixed, increasing Ra leads to an increase in Pe while
 168 the ratios $K_{\mathcal{T}}/K$ and $K_{\mathcal{T}}^z/K$ remain relatively constant in the parameter range considered
 169 (Table 1). Increasing q^* with all other parameters fixed shows a general increase in Pe (see
 170 also Figure 1), a slight increase in $K_{\mathcal{T}}/K$ and little variation in $K_{\mathcal{T}}^z/K$, which is a small
 171 fraction of the total energy in all models.

172 In the next two sections we analyse the models in Table 1 in detail. In the subsequent
 173 discussion $\phi = 0^\circ$ corresponds to the rightmost edge of the equatorial projections and is
 174 the longitude of minimum heat-flux; the maximum heat-flux is imposed at $\phi = 180^\circ$. The
 175 western hemisphere, which is subject to a higher than average heat-flux, is defined as the
 176 region $90^\circ < \phi \leq 270^\circ$ and the eastern hemisphere, which is subjected to a lower than
 177 average heat-flux, is defined as the region $-90^\circ < \phi \leq 90^\circ$.

178 3.1. Y_1^1 inner boundary condition

179 Figure 2 shows four models with $Ra = 90$ that differ only by the value of q^* . The
 180 snapshots are taken at time $t = 11$ of Figure 1a. With homogeneous boundaries ($q^* = 0$)
 181 the familiar pattern of spiralling columnar rolls aligned with the rotation axis, a feature of
 182 moderate Pr and low Ra convection, is obtained (Zhang, 1992). The prograde drift speed
 183 of the columns varies with radius and hence the convection is characterised by different
 184 wavenumbers at different distances from the rotation axis (e.g. Sun et al., 1993; Tilgner

185 and Busse, 1997). The pattern of temperature anomalies in the equatorial plane is well-
 186 correlated with radial velocity. The m -spectrum of kinetic energy (Figure 1) is characterised
 187 by a peak at $m = 0$, and broad peaks around the most unstable mode and its overtones.

188 Imposing a Y_1^1 heat-flux variation at the inner boundary significantly alters the large-
 189 scale flow pattern as q^* is increased above zero. For $Ra = 90$ we identify three broad flow
 190 regimes. For $q^* \leq 0.6$ the homogeneous flow pattern is modulated by the presence of the
 191 Y_1^1 boundary anomaly. Figure 2 shows that, for $q^* = 0.6$, the velocity field in the western
 192 hemisphere has a higher amplitude and a larger characteristic azimuthal wavenumber than
 193 in the eastern hemisphere. The columnar rolls drift in the prograde sense in this model,
 194 but accelerate when passing through the eastern (low heat-flux) hemisphere and decelerate
 195 when passing through the western hemisphere. Similar behaviour was found by Zhang
 196 and Gubbins (1993) in a convection model with lateral variations at the OB. Temperature
 197 anomalies near the IB are predominantly negative in the region $0^\circ < \phi \leq 180^\circ$ and positive
 198 in the region $180^\circ < \phi \leq 360^\circ$; a similar phase shift of temperature anomalies with respect
 199 to the boundary anomalies has been observed in models of convection with lateral OB
 200 variations (Olson, 2003).

201 For $0.6 < q^* \leq 1.4$ the $m = 1$ mode becomes dominant in the m -spectrum of the kinetic
 202 energy (Figure 1) and convection columns are absent in parts of the eastern hemisphere.
 203 Very weak radial motions are observed between $-90^\circ < \phi \leq 0^\circ$ as shown in Figure 2 for
 204 $q^* = 1.4$. This region is characterised by strong prograde and retrograde azimuthal jets that
 205 are established near the IB at $\phi \approx 180^\circ$ and spiral outwards, terminating when they reach
 206 the OB. Strong vertical and radial gradients in azimuthal velocity are evident in the region
 207 spanned by the jets. The pattern of temperature anomalies is dominated by an $m = 1$
 208 component and strong gradients in the region where the jets are formed.

209 Finally, for $q^* > 1.4$ the flow patterns are almost stationary as suggested by the kinetic
 210 energy time-series in Figure 1a. Figure 2 for $q^* = 4.2$ shows that the azimuthal jets become
 211 stronger and have greater lateral extent than at lower values of q^* . The amplitude of vertical
 212 and radial gradients in azimuthal velocity in the region spanned by the jets also increase
 213 with q^* . Strong upwelling and downwelling regions are visible in the plot of u_r near the
 214 locations where the azimuthal jets are initiated and terminated due to interaction with the
 215 OB, but away from these regions the radial velocity is very weak. Temperature gradients
 216 are strong in the region where the azimuthal jets are formed and departures from the basic
 217 state are significant across broad regions of the shell.

218 The large-scale flow patterns described above for $q^* \geq 1.4$ are reminiscent of those found
 219 by Grote and Busse (2001) and Busse et al. (2003) in simulations of rotating convection
 220 with homogeneous boundaries. In their models, convection columns are sheared by a strong
 221 azimuthal zonal ($m = 0$) flow driven by Reynolds stresses; the zonal flow dominates in large
 222 regions of the shell where radial motion is severely inhibited. Although a large-scale shear is
 223 apparent in our models for $q^* \geq 1.4$ there are three factors suggesting that it is driven by a
 224 different mechanism to that described by Grote and Busse (2001). Firstly, our values of Ra
 225 are much smaller than those used by Grote and Busse (2001); indeed, with a homogeneous
 226 IB condition and $Ra = 90$, Figure 2 shows that convection columns are not confined to a
 227 particular longitudinal band. Secondly, the region where convection columns are observed in

228 the Grote and Busse (2001) simulations is not fixed in space, in contrast to our models where
 229 this region remains in the western hemisphere. Finally, our models contain only $\sim 1/10$ th
 230 of the total energy in zonal components (Table 1), suggesting that the shear generated by
 231 large-scale nonzonal flows could greatly exceed shear generated by the zonal flow. We now
 232 explore these three points in detail by investigating the mechanisms that drive the azimuthal
 233 flows observed for $q^* \geq 1.4$ (Figure 2). We first consider the azimuthal zonal flow, which we
 234 denote u_ϕ^z , and then focus on the nonzonal azimuthal flow, which is denoted u_ϕ^{nz} hereafter.

235 There are two main driving mechanisms for u_ϕ^z (e.g. Cardin and Olson, 1994; Aubert
 236 et al., 2003). The first is due to Reynolds stresses arising from the convection columns,
 237 which drive a zonal flow with cylindrical symmetry that tends to be strongly retrograde
 238 near the IB (Busse, 1970; Cardin and Olson, 1994) and slightly retrograde (Cardin and
 239 Olson, 1994) or prograde (Glatzmaier and Olson, 1993) near the OB. The second driving
 240 force for u_ϕ^z arises because more heat is lost in equatorial regions than polar regions, which
 241 sets up axisymmetric latitudinal temperature gradients that drive zonal flows with shear in
 242 the vertical z direction. To distinguish between these two mechanisms we follow Glatzmaier
 243 and Olson (1993) and define the geostrophic wind as the portion of the zonal flow that
 244 is uniform in the axial direction and the remainder, which contains vertical shear, as the
 245 ageostrophic wind. We compute u_ϕ^z by retaining only the $m = 0$ component of the velocity
 246 field, and the geostrophic wind, $[u]_\phi^z$ by averaging this flow over z . The averaging operation
 247 denoted by square brackets is defined by

$$\square = \frac{1}{2L} \int_L^{-L} dz, \quad L = \sqrt{r_o^2 - s^2}, \quad (10)$$

248 where $s = r \sin(\theta)$ is cylindrical radius. Figure 3 shows u_ϕ^z and $[u]_\phi^z$ for $q^* = 1.4$ and 4.2.
 249 The zonal flow is westward (retrograde) near the tangent cylinder (the imaginary cylinder
 250 parallel to the rotation axis that touches the inner core equator) for all values of q^* including
 251 $q^* = 0$. Near the OB, u_ϕ^z is slightly prograde at mid-latitudes for low values of q^* ; for $q^* \geq 2.8$
 252 the prograde u_ϕ^z at mid-latitudes is approximately half the value of the retrograde flow near
 253 the IB. These features are also reflected in the profiles of $[u]_\phi^z$ in Figure 3. Increasing q^*
 254 produces a mild increase in u_ϕ^z , presumably due to nonlinear interaction with the large-scale
 255 boundary forcing, and also causes an increase in $[u]_\phi^z$; the ratio $[u]_\phi^z/u_\phi^z$ does not show a
 256 strong dependence on q^* for the particular Ra we have considered. We conclude that, for
 257 the models considered, the geostrophic and ageostrophic contributions to the zonal flow are
 258 comparable.

259 Our models contain a large-scale nonzonal azimuthal flow, u_ϕ^{nz} , that dramatically in-
 260 creases in amplitude as q^* increases (compare the meridional sections in Figures 2 and 3).
 261 The variation of u_ϕ with z seen in both Figures suggests a significant thermal wind exists
 262 in our models, as has been found in other simulations with inhomogeneous boundary condi-
 263 tions (e.g. Zhang, 1992; Sreenivasan, 2009). Taking the curl of equation (3) with the viscous
 264 force and acceleration term omitted gives

$$\frac{\partial \mathbf{u}}{\partial z} + Ra \nabla \times (T \mathbf{r}) - \frac{E}{Pr} \nabla \times [(\mathbf{u} \cdot \nabla) \mathbf{u}] = 0; \quad (11)$$

265 omitting the contribution from the divergence of the Reynolds stress (the last term) gives
 266 the thermal wind balance. Figure 4 shows the terms in (11) and their sum for $q^* = 4.2$.
 267 For this model the first two terms in (11) are over an order of magnitude larger than the
 268 last term. The remainder after summing terms on the left-hand side of (11) is close to zero
 269 outside the tangent cylinder as shown in the rightmost column of Figure 4. These results
 270 imply that a thermal wind balance holds for the model with $q^* = 4.2$. Further calculations
 271 (not shown) indicate that this balance holds well for all models conducted at $Ra = 90$.
 272 Sumita and Olson (2002) noted that regions where $\partial u_\phi / \partial z > 0$ and where $|u_\phi|$ decreases
 273 with z imply $u_\phi < 0$ if the thermal wind balance applies. Similarly, $\partial u_\phi / \partial z > 0$ and $|u_\phi|$
 274 increasing with z implies $u_\phi > 0$; $\partial u_\phi / \partial z < 0$ and $|u_\phi|$ decreasing with z implies $u_\phi > 0$;
 275 $\partial u_\phi / \partial z < 0$ and $|u_\phi|$ increasing with z implies $u_\phi < 0$. The meridional sections shown in
 276 Figure 5 for $q^* = 4.2$ indicate that the above relations are reasonably well-satisfied and
 277 further calculations for models that contain large-scale azimuthal jets (see Figure 2) give
 278 similar results. These results suggest that, in the models described above, the dominant
 279 driving force for the nonzonal azimuthal flow, u_ϕ^{nz} , is a thermal wind. Furthermore, Figure 4
 280 indicates that a thermal wind is the dominant driving force for the ageostrophic contribution
 281 to the azimuthal zonal flow, u_ϕ^z .

282 Figures 3 and 5 show that changes in sign of u_ϕ^z and u_ϕ^{nz} occur at almost the same (cylin-
 283 drical) radii in regions where radial flow is weak and azimuthal flow dominates, suggesting
 284 that shear due to the zonal flow is reinforced by shear due to the nonzonal azimuthal flow
 285 driven by the inhomogeneous boundary. This explains why convection columns are not con-
 286 fined to a particular longitudinal band in models with no boundary forcing: shear in the
 287 zonal flow alone is not strong enough to break down the convection columns. The region
 288 where the columnar rolls can persist is determined by the amplitude of the shear produced
 289 by u_ϕ^z and u_ϕ^{nz} . For $q^* \geq 2.8$, u_r and u_ϕ^{nz} are both strongest above the maximum IB heat-flux
 290 at $\phi = 180^\circ$, but the shear due to the strong u_ϕ^{nz} is sufficient to break down convection
 291 columns directly east of the maximum heat-flux until u_ϕ^{nz} weakens sufficiently for columns
 292 to reemerge around $\phi = 0^\circ$. At lower values of q^* the u_ϕ^{nz} driven by the thermal wind is
 293 not strong enough to shear convection columns in the western hemisphere where the high
 294 heat-flux drives strong radial motions; however, in the eastern hemisphere, the combined
 295 action of zonal and nonzonal azimuthal flows dominates over the relatively weak radial mo-
 296 tions. This explains why the region where convection columns persist is always located in the
 297 hemisphere where the IB heat-flux is higher than the average. Finally, our analysis suggests
 298 that the large-scale azimuthal flows in the models described above are driven predominantly
 299 by a thermal wind; Reynold's stresses play a secondary role.

300 For $Ra = 150$ and $Ra = 225$ we did not obtain quasi-stationary solutions for any value
 301 of q^* considered. Higher values of Ra lead to more energy in small-scales compared to those
 302 with $Ra = 90$, but the large-scale features are very similar to those described above for
 303 $Ra = 90$. Figure 6 shows time-averaged flow patterns with $q^* = 1.4$ and $Ra = 90, 150, 225$.
 304 Instantaneous and time-averaged flows for $Ra = 90$ show the same basic features, as could be
 305 anticipated by comparing the time-averaged and instantaneous velocity spectra in Figure 1.
 306 Interestingly, the time-averaged flow for $q^* = 1.4$ indicates that upwellings and downwellings
 307 in the western hemisphere, with a characteristic lengthscale much smaller than that of the

308 imposed boundary anomaly, occur in preferred locations. The superposition of scales in
 309 flows forced by inhomogeneous outer boundary conditions was noted by Davies et al. (2009).
 310 Equatorial sections for $Ra = 150$ and 225 reveal large-scale nonzonal azimuthal flows similar
 311 to those studied in detail for $Ra = 90$ and $q^* = 4.2$; indeed, applying the same analysis to
 312 these cases suggests that the mechanisms inferred to drive the zonal azimuthal flow u_ϕ^z , and
 313 the nonzonal azimuthal flow u_ϕ^{nz} , are the same as those discussed for models with $Ra = 90$.
 314 Increasing Ra for fixed q^* does not change the amplitude of u_ϕ^{nz} significantly, but strengthens
 315 u_ϕ^z (Table 1) due to increased Reynolds stresses and axisymmetric latitudinal temperature
 316 gradients. The combined shear due to u_ϕ^z and u_ϕ^{nz} (which are well-correlated as above)
 317 produces similar large-scale effects at $Ra = 150, 225$ as for $Ra = 90$. These results suggest
 318 that the behaviour described for solutions with $Ra = 90$ is broadly characteristic of the
 319 behaviour across the range of Ra considered.

320 3.2. Y_1^1 outer boundary condition

321 In this section we briefly discuss the effect of imposing a Y_1^1 boundary anomaly at the OB
 322 with a homogeneous IB. The model parameters are the same as used in §3.1, but we consider
 323 only $Ra = 90$. Simulations were conducted with $q^* = 11.2$ and $q^* = 34.2$ (see Table 1),
 324 corresponding to OB anomalies that are equal in magnitude to the IB anomalies imposed in
 325 the models with $q^* = 1.4$ and 4.2 respectively. No quasi-steady solutions were obtained for
 326 models with Y_1^1 OB anomalies at $Ra = 90$, unlike models with Y_1^1 IB anomalies where such
 327 solutions were obtained for $Ra = 90$ and $q^* \geq 2.8$. Simulations at higher values of Ra were
 328 not conducted, but quasi-steady solutions are not anticipated based on the results of §3.1.

329 Figure 7 shows a snapshot of the flow pattern for $Ra = 90$ and $q^* = 34.2$. Temporal
 330 variations are most apparent outside the tangent cylinder near the IB, where a sequence of
 331 columnar rolls reminiscent of the pattern of homogeneous ($q^* = 0$) convection (see Figure 2)
 332 drift predominantly in the prograde sense. A cluster of rolls are located beneath the OB
 333 under the region of high heat-flux and remain in this location for the length of our simulation
 334 (6 time units). A previous study (Davies et al., 2009) with an imposed Y_2^2 OB condition
 335 found two such clusters. These results suggest that the number of clusters is determined
 336 by the azimuthal wavenumber of the imposed boundary anomaly. Large-scale nonzonal
 337 azimuthal flows are generated near the OB but do not penetrate all the way to the IB.

338 Figure 8 shows the ϕ -component of the thermal wind balance (equation (11)) for $Ra = 90$
 339 and $q^* = 34.2$. Both terms are large and tend to balance near the OB; however, the
 340 amplitude of the thermal wind decreases significantly with depth. Conducting the analysis
 341 of §3.1 suggests that the large-scale nonzonal azimuthal flows near the OB are driven by the
 342 thermal wind resulting from the OB heat-flux anomalies; these flows are much stronger than
 343 those obtained with a Y_1^1 IB condition (see Table 1), which we attribute to the larger surface
 344 area of the OB giving rise to a stronger thermal wind. Azimuthal flows are much weaker and
 345 contain more small-scale structure at depth where the thermal wind is weak. This, together
 346 with the fact that the homogeneous system is driven from below, suggests that the effects
 347 of OB anomalies do not penetrate far enough into the shell to stop fluid near the IB from
 348 drifting, as it would do in the absence of boundary anomalies. For this particular model
 349 it appears that the Y_1^1 OB condition has less overall influence on the spatial and temporal

350 characteristics of the flow than a Y_1^1 IB condition. We attribute this to the fact that, in our
351 simulations, the IB condition is imposed in the same location as the buoyancy source for
352 free convection.

353 4. Discussion and conclusions

354 We have performed numerical simulations to investigate the effects of a translating inner
355 core on outer core convection. The novel feature of our model is that convection in the
356 outer core is driven non-uniformly from below. Many previous studies have investigated the
357 effects of laterally-varying outer boundary conditions on rotating convection (e.g. Zhang,
358 1992; Zhang and Gubbins, 1993; Davies et al., 2009) and magnetic field generation (e.g.
359 Olson and Christensen, 2002; Willis et al., 2007; Sreenivasan, 2009) in spherical shells. By
360 contrast, laterally-varying inner boundary conditions have received very little attention, save
361 for an investigation into possible long-term asymmetry in the geomagnetic field by Olson
362 and Deguen (2012). Studies with laterally-varying outer boundary conditions generally use
363 a pattern of boundary anomalies inferred from seismic tomography, a complex combination
364 of spherical harmonics, or the largest harmonic in this pattern, which is Y_2^2 . Conversely, the
365 large-scale pattern imposed by inner core translation is a spherical harmonic Y_1^1 . Motivated
366 by these issues, we used an idealised nonmagnetic model of thermally-driven convection in
367 a rotating spherical shell designed to highlight the effects of the imposed Y_1^1 inner boundary
368 heat-flux. Nonmagnetic models reduce computational costs, allowing a suite of simulations
369 to be conducted, and afford theoretical simplifications compared to geodynamo simulations.
370 Our results for the simpler hydrodynamic problem will hopefully guide future research into
371 geodynamo models with laterally-varying inner boundary conditions.

372 The suite of simulations conducted for this work use an Ekman number that is low enough
373 for the dynamics to be rotation-dominated and focus on low Rayleigh numbers, where the
374 influence of the boundary condition is expected to be prominent. Higher Rayleigh numbers
375 could lead to a weakening of boundary effects at the values of q^* (which measures the
376 amplitude of boundary anomalies) used in this work, but higher values of q^* may lead to
377 significant boundary effects even when the Rayleigh number is highly supercritical. Such a
378 regime cannot be ruled out given the significant uncertainties in the value of q^* appropriate
379 for the Earth.

380 In our models, increasing q^* with all other parameters fixed leads to significant changes in
381 the large-scale flow pattern compared to the solution with a homogeneous inner boundary
382 ($q^* = 0$). The most striking feature is the development of spiralling azimuthal jets that
383 span large portions of the shell. Radial motion tends to be weak where the azimuthal jets
384 are strong. Vigorous convection becomes increasingly confined to localised regions as q^*
385 increases; these regions do not drift and are always located in the hemisphere where the
386 boundary heat-flux is higher than the average.

387 We explored the processes responsible for generating the localised regions of convection
388 that emerge at large q^* , focusing on shear generated by the large-scale zonal and nonzonal
389 azimuthal flows. Zonal flows generally account for only a small fraction of the total kinetic
390 energy in our models, partly due to our use of no-slip boundary conditions (Christensen,

391 2002) and partly due to choice of relatively low Ra . The energy in the zonal flow remains a
392 small fraction of the kinetic energy for all values of q^* considered. Large-scale nonzonal az-
393 imuthal jets significantly increase in amplitude with q^* and tend to dominate the zonal flows
394 when the boundary forcing is strong. Our analysis suggests that the large-scale nonzonal
395 azimuthal jets are driven by a thermal wind resulting from the boundary anomalies and that
396 the shear generated by these jets leads to the destruction of columnar convection rolls (that
397 would otherwise exist in the absence of boundary anomalies) in regions where the shearing
398 flow is much greater than the amplitude of the radial flow. Thermal winds were found to be
399 more important for driving large-scale flows than Reynold's stresses at high values of q^* .

400 Applying a Y_1^1 heat-flux pattern at the outer boundary, with a spherically symmetric
401 inner boundary, appears to exert a weaker influence on fluid far from the inhomogeneous
402 boundary compared to a model with the same parameter values and a Y_1^1 inner boundary
403 condition. We suggest that this occurs in the model because outer boundary effects are
404 weakest where the buoyancy force driving homogeneous convection is strongest. Models
405 with inhomogeneous inner and outer boundaries designed to simulate outer core-mantle and
406 outer core-inner core interactions are needed to further explore this potentially significant
407 result.

408 The effects of the inner boundary condition are visible in instantaneous and time-averaged
409 surface flows even for low values of q^* . Figure 9 shows that the surface expression of the
410 lateral inner boundary anomalies is an amplitude difference between the flow in the eastern
411 and western hemispheres. The amplitude difference increases with q^* . At the highest values
412 of q^* there is a clear signature of the large-scale azimuthal flows that are generated near
413 the inner boundary and spiral outward. Close correspondence between magnetic and non-
414 magnetic flows found in models with laterally-varying outer boundary conditions (e.g. Willis
415 et al., 2007) raise the possibility that flows of this type may arise in geodynamo models.
416 This may be the case if the Lorentz force does not significantly alter the largest scales of
417 the flow.

418 Our principle conclusion is that the presence of thermal inner boundary anomalies can
419 significantly affect the dynamics of convection in a rotating spherical shell. This result
420 appears consistent with the models of Olson and Deguen (2012), which include the effect
421 of a magnetic field but operate at lower rotation rates than those considered here. Future
422 work is needed to assess the role of laterally-varying thermal inner boundary conditions at
423 rapid rotation rates with the inclusion of the magnetic field.

Table 1: Convection simulations used in this work. All simulations use $Pr = 1$ and $E = 10^{-5}$. Ra is the Rayleigh number based on the average boundary heat-flux. All models employ a Y_1^1 inner boundary condition and a spherically symmetric outer boundary condition except those denoted with an asterisk, which employ a Y_1^1 outer boundary condition and a spherically symmetric inner boundary condition. Velocity is measured in units of the Péclet number, $Pe = Ud/\kappa = \sqrt{2K/V_s}$, where $V_s = 14.59$ is the nondimensional volume of the spherical shell. K is the total kinetic energy; $K_{\mathcal{T}}$ the toroidal kinetic energy; and $K_{\mathcal{T}}^z$ the zonal toroidal kinetic energy. Each run spans six thermal diffusion time units following an initial transient phase.

Figure 1: a) kinetic energy plotted against time for different values of q^* (top). Time is measured in units of d^2/κ . b) and c) kinetic energy as a function of harmonic degree l and order m plotted up to degree and order $l = m = 30$ at time $t = 11$ in a) (solid lines) and averaged over the period of time shown in a) (dashed lines). Other parameter values are $E = 10^{-5}$, $Pr = 1$, $Ra = 90$. Note that spherical harmonics up to degree and order 80 were retained in the solutions and spectra are plotted up to $l = m = 30$ for clarity.

Figure 2: Snapshots of simulations at $t = 11$ in Figure 1a. From top to bottom: models with $q^* = 0, 0.6, 1.4$ and 4.2 . Other parameter values are $E = 10^{-5}$, $Pr = 1$, $Ra = 90$. From left to right: u_r in the equatorial plane; u_ϕ in the equatorial plane; temperature perturbation with the spherically symmetric (Y_0^0) component of the spherical harmonic expansion removed; u_ϕ in the meridional plane at $\phi = 270^\circ$. $\phi = 0^\circ$ corresponds to the rightmost edge of the equatorial sections and is the longitude of minimum heat-flux; maximum heat-flux is imposed at $\phi = 180^\circ$.

Figure 3: Snapshots of the azimuthal component of the zonal flow, u_ϕ^z , for $q^* = 1.4$ (left) and $q^* = 4.2$ (middle). Snapshots of the vertically (z) averaged azimuthal component of the zonal flow, $[u_\phi^z]$, as a function of radius for various values of q^* (right). Snapshots are taken at $t = 11$ in Figure 1a. Other parameter values are $E = 10^{-5}$, $Pr = 1$, $Ra = 90$.

Figure 4: Snapshots, taken at $t = 11$ in Figure 1a, of the θ (top) and ϕ (bottom) components of equation (11) for a model with $E = 10^{-5}$, $Pr = 1$, $Ra = 90$, $q^* = 4.2$ and a Y_1^1 inner boundary condition. The first two columns show the thermal wind balance. The plots show $\partial u_\theta / \partial z$ (column 1, top), $-(Ra/r \sin \theta) \partial T / \partial \phi$ (column 2, top), $\partial u_\phi / \partial z$ (column 1, bottom), and $(Ra/r) \partial T / \partial \theta$ (column 2, bottom). Column 3 shows the θ (top) and ϕ (bottom) components of the term $(E/Pr) \nabla \times [(\mathbf{u} \cdot \nabla) \mathbf{u}]$ in equation (11). Column 4 shows the remainder after adding the fields in columns 1–3. All images are volume rendered with the equatorial plane highlighted for clarity. Boundary layers have been removed from the plots as they are sources of vorticity, which tend to obscure features in the bulk of the shell.

Figure 5: Snapshots of the azimuthal component of the nonzonal ($m \neq 0$) flow, u_ϕ^{nz} , at $\phi = 180^\circ$ (left), 225° , 270° and 315° (right) for $q^* = 4.2$. Snapshots are taken at $t = 11$ in Figure 1a. Other parameter values are $E = 10^{-5}$, $Pr = 1$, $Ra = 90$.

Figure 6: Time-averaged flows for $E = 10^{-5}$, $Pr = 1$ and $q^* = 1.4$. u_r (top) and u_ϕ (bottom) in the equatorial plane for $Ra = 90$ (left), 150 (middle), and 225 (right). Time-averages span 6 time units, which are measured in units of d^2/κ . $\phi = 0^\circ$ corresponds to the rightmost edge of the plots and is the longitude of minimum heat-flux; maximum heat-flux is imposed at $\phi = 180^\circ$.

Figure 7: Snapshots of u_r (left) and u_ϕ (right) in the equatorial plane for $Ra = 90$ and $q^* = 34.2$ with a Y_1^1 outer boundary condition. $\phi = 0^\circ$ corresponds to the rightmost edge of the plots and is the longitude of minimum heat-flux; maximum heat-flux is imposed at $\phi = 180^\circ$. Other parameter values are $E = 10^{-5}$, $Pr = 1$, $Ra = 90$.

Figure 8: Snapshots of the ϕ component of the thermal wind balance (first two terms in equation (11)) for a model with $E = 10^{-5}$, $Pr = 1$, $Ra = 90$ and $q^* = 34.2$ with a Y_1^1 outer boundary condition. The plots show $\partial u_\phi / \partial z$ (left), $(Ra/r)\partial T / \partial \theta$ (middle), and the remainder after adding the fields in columns 1 and 2 (right). All images are volume rendered with the equatorial plane highlighted for clarity. Boundary layers have been removed from the plots as they are sources of vorticity, which tend to obscure features in the bulk of the shell.

Figure 9: Snapshots (left) and time-averages (right) of u_ϕ in Mollweide projection for $Ra = 90$ and $q^* = 0.3$ (top), $Ra = 90$ and $q^* = 1.4$ (middle) and $Ra = 225$ and $q^* = 1.4$ (bottom). Snapshots are taken at $t = 11$ of Figure 1a. Time-averages span 6 time units, which are measured in units of d^2/κ . Projections are taken at $r = 0.95r_o$, i.e. just beneath the outer boundary. Note the amplitude difference between the western hemisphere (left half of each projection) and the eastern hemisphere (right half).
