## 38 Abstract

39 Between a few tons to several hundred tons of meteoric material enters the  
40 Earth's atmosphere each day, and most of this material is ablated and vaporized  
41 in the 70 to 120 km altitude region. The subsequent chemical conversion, re-  
42 condensation and coagulation of this evaporated material are thought to form  
43 nanometre sized meteoric smoke particles (MSPs). These smoke particles are  
44 then subject to further coagulation, sedimentation and global transport by the  
45 mesospheric circulation. MSPs have been proposed as a key player in the  
46 formation and evolution of ice particle layers around the mesopause region, i.e.  
47 noctilucent clouds (NLC) and polar mesosphere summer echoes (PMSE). MSPs  
48 have also been implicated in mesospheric heterogeneous chemistry to influence  
49 the mesospheric odd oxygen/odd hydrogen ( $O_x/HO_x$ ) chemistry, to play an  
50 important role in the mesospheric charge balance, and to be a significant  
51 component of stratospheric aerosol and enhance the depletion of  $O_3$ .

52 Despite their apparent importance, little is known about the properties of MSPs  
53 and none of the hypotheses can be verified without direct evidence of the  
54 existence, altitude and size distribution, shape and elemental composition. The  
55 aim of the MAGIC project (Mesospheric Aerosol – Genesis, Interaction and  
56 Composition) was to develop an instrument and analysis techniques to sample  
57 for the first time MSPs in the mesosphere and return them to the ground for  
58 detailed analysis in the laboratory. MAGIC meteoric smoke particle samplers  
59 have been flown on several sounding rocket payloads between 2005 and 2011.  
60 Several of these flights concerned non-summer mesosphere conditions when  
61 pure MSP populations can be expected. Other flights concerned high latitude  
62 summer conditions when MSPs are expected to be contained in ice particles in  
63 the upper mesosphere. In this paper we present the MAGIC project and describe  
64 the MAGIC MSP sampler, the measurement procedure and laboratory analysis.  
65 We also present the attempts to retrieve MSPs from these flights, the challenges  
66 inherent to the sampling of nanometre sized particles and the subsequent  
67 analysis of the sampled material, and thoughts for the future. Despite substantial  
68 experimental efforts, the MAGIC project has so far failed to provide conclusive  
69 results. While particles with elemental composition similar to what is to be  
70 expected from MSPs have been found, the analysis has been compromised by

71 challenges with different types of contamination and uncertainties in the sticking  
72 efficiency of the particles on the sampling surfaces.  
73

## 74 1. Introduction

75 The Earth's atmosphere is constantly bombarded by meteoric material. The total  
76 amount of this incoming material is a subject of controversy (Plane, 2012) with  
77 estimates ranging from a few tons to several hundred tons per day (Hughes,  
78 1978; Love and Brownlee, 1993; Ceplecha et al., 1998; Cziczo et al., 2001;  
79 Mathews et al., 2001; Gabrielli et al., 2004; Plane, 2004; von Zahn, 2005). Most of  
80 this material is expected to vaporise in the altitude region 70 – 120 km during  
81 atmospheric entry (e.g. Ceplecha et al., 1998; Vondrak et al., 2008). It is well  
82 known that this ablation is the source of the global layers of metal atoms and  
83 ions that are observed by ground-based (e.g. Chamberlain et al., 1958; Bowman  
84 et al., 1969; Kane and Gardner, 1993; Alpers et al., 1996; Eska et al., 1998; Plane,  
85 2003) and satellite- and rocket-borne (e.g. Donahue and Meier, 1967; Donahue et  
86 al., 1972; Newman, 1988; Kopp, 1997; Aikin et al., 2004; Fussen et al., 2010;  
87 Hedin and Gumbel, 2011) instruments in the mesosphere and lower  
88 thermosphere (MLT) region. Chemical conversion and subsequent re-  
89 condensation and coagulation of the vaporised material is thought to give rise to  
90 tiny nanometre size meteoric smoke particles, MSPs, which are then subject to  
91 further coagulation, sedimentation and global transport by the mesospheric  
92 meridional circulation (e.g. Rosinski and Snow, 1961; Hunten et al., 1980;  
93 Kalashnikova et al. 2000; Gabrielli et al., 2004; Megner et al., 2006; 2008a;  
94 2008b). The general circulation of the atmosphere transports the MSPs away  
95 from the summer pole towards the winter pole and into the polar winter vortex  
96 (Megner, 2007; Bardeen et al., 2008; Megner et al., 2008a; 2008b), thus  
97 producing a strong annual variation. The general composition of the meteoric  
98 smoke material is thought to reflect the composition of the incoming meteorite  
99 material. However, due to differential ablation processes and the altitude-  
100 dependent chemical environment, the detailed smoke composition is expected to  
101 depend on the history of the individual meteoric particles (e.g. McNeil et al.,  
102 1998; Kalashnikova et al., 2000). Considering the meteoric influx, major vapour  
103 components are presumably silicon, iron and magnesium, with minor  
104 contributions from other metals like sodium, aluminium, potassium, calcium,  
105 lithium etc. Following gas phase chemical transformation prior to re-  
106 condensation, these compounds are likely to be present in the form of oxides,

107 hydroxides and carbonates in the resulting smoke particles (e.g. Plane, 2003; Self  
108 and Plane, 2003; Plane and Whalley, 2012).

109 Basic information about MSP properties is today available from optical  
110 occultation measurements (Hervig et al., 2009, 2012) and, more indirectly, as a  
111 fraction of the particles is expected to be charged by the surrounding plasma,  
112 from measurements of heavy charge carriers from sounding rockets (Schulte and  
113 Arnold, 1992; Havnes et al., 1996; Gelinas et al., 1998; Horányi et al., 2000;  
114 Croskey et al., 2001; Robertson et al., 2004, 2009, 2013; Lynch et al., 2005;  
115 Barjatya and Swenson, 2006; Smiley et al., 2006; Havnes and Næsheim, 2007;  
116 Amyx et al., 2008; Strelnikova et al., 2009; Rapp et al., 2005, 2010, 2012; Havnes  
117 et al., 2013), and from incoherent scatter radars (Rapp et al., 2007; Strelnikova et  
118 al., 2007; Fentzke et al., 2009). Experimental studies have been performed in the  
119 laboratory (Saunders and Plane, 2006; 2011), but much of the existing  
120 knowledge about MSPs relies on model results (e.g. Hunten et al., 1980; Megner  
121 et al., 2006, 2008a, 2008b; Bardeen et al., 2008). It has been shown that  
122 substantial amounts of particles of meteoric origin are present in the  
123 stratosphere (e.g. Murphy et al., 1998; Cziczo et al., 2001) and that meteoric  
124 smoke particles reach the Earth's surface (e.g. Gabrielli et al., 2004; Lanci and  
125 Kent, 2006; Dhomse et al., 2013), but no equivalent measurements of particles  
126 have ever been achieved in the mesosphere. Attempts were made in the 1960s to  
127 sample mesospheric aerosol from sounding rockets (e.g. Hemenway et al., 1964;  
128 Soberman and Hemenway, 1965; Farlow et al, 1970), but none of the  
129 measurements resulted in any conclusive results. Very recently, a student  
130 experiment attempted to sample particles from a sounding rocket launched  
131 within the REXUS/BEXUS (Rocket/Balloon Experiment for University Students)  
132 programme, a bi-lateral cooperation between the Swedish National Space Board  
133 (SNSB) and the German Aerospace Center (DLR), but results from the analysis is  
134 not yet available (see Reid et al. (2013) for details about the experiment).

135 Although there is only indirect evidence of their existence in the mesosphere,  
136 MSPs have been proposed as a key player in the formation and evolution of  
137 several observed mesospheric phenomena. Smoke particles are today recognised  
138 as the most likely candidate for condensation nuclei for mesospheric ice particles  
139 (Rapp and Thomas, 2006) and hence phenomena such as noctilucent clouds, NLC

140 (Gadsden and Schröder, 1989; Thomas, 1991), or polar mesospheric clouds,  
141 PMC, and polar mesosphere summer echoes, PMSE (Rapp and Lübken, 2004).  
142 These water ice particles (Hervig et al., 2001) are probably not pure ice with just  
143 one MSP as nuclei, but more likely “dirty” ice particles with a large amount of  
144 MSPs embedded in them along with metal atoms and molecules from meteoric  
145 ablation (Havnes and Næsheim, 2007; Hervig et al., 2012; Kassa et al., 2012;  
146 Havnes et al., 2013). Smoke particles are also believed to be responsible for the  
147 polar mesosphere winter echoes (PMWE) observed by radars outside the PMSE  
148 season (e.g. Zeller et al., 2006). With the advent of more powerful radars, these  
149 winter echoes have now been observed also during summer below the much  
150 stronger PMSE (Latteck et al., 2012). Heterogeneous chemistry has been  
151 suggested to take place on the surfaces of smoke particles. An example is the  
152 proposed catalytic recombination of O and H<sub>2</sub> as a local source of water vapour  
153 in the mesosphere to explain observations of mesospheric HO<sub>x</sub> chemistry and  
154 unexpectedly high water concentrations (Summers and Siskind, 1999; Conway et  
155 al., 2000). By scavenging various gas-phase products of meteoric ablation, MSPs  
156 are thought to act as a sink in mesospheric metal chemistry (Plane, 2004). Smoke  
157 particles can also efficiently scavenge free electrons and ions and can thus play a  
158 substantial role in the D-region charge balance (Rapp and Lübken, 2001; Rapp,  
159 2009; Friedrich et al., 2011). This charging may in turn strongly affect smoke  
160 coagulation and ice particle nucleation processes (Gumbel and Megner, 2009;  
161 Megner and Gumbel, 2009). The strong downward circulation in the winter polar  
162 vortex can efficiently transport MSPs down into the winter stratosphere. Here,  
163 MSPs can be involved in stratospheric chemistry and the microphysics of polar  
164 stratospheric clouds (PSC) and thus have important effects on ozone chemistry  
165 (e.g. Murad et al., 1981; Curtius et al., 2005; Voigt et al., 2005, Saunders et al.,  
166 2012). Very recently Dhomse et al. (2013) predicted high deposition of MSPs to  
167 occur at middle latitudes, providing a significant source of Fe fertilization to the  
168 Southern Ocean.

169 Despite their apparent importance, little is known about the properties of  
170 meteoric smoke particles and none of the hypotheses above can be verified  
171 without direct evidence of their existence, altitude and size distribution, and  
172 composition. The objective of the MAGIC project (Mesospheric Aerosol – Genesis,

173 Interaction and Composition) was to quantitatively answer fundamental  
174 questions about the properties of MSPs in the mesosphere:

- 175 • Do re-condensed smoke particles of meteoric origin exist in the  
176 mesosphere?
- 177 • What is their number density, shape and size distribution?
- 178 • What is their spatial distribution and how are they transported?
- 179 • What is their elemental and molecular composition?
- 180 • How do they interact with their mesospheric and ionospheric  
181 environment?

182

183 To address these questions, an instrument was designed and built to directly  
184 sample meteoric smoke particles in the mesosphere and return them to the  
185 ground for detailed laboratory investigations. In this paper we describe the  
186 MAGIC meteoric smoke particle sampler and present attempts to directly sample  
187 MSPs. In section 2 the ideas behind the MAGIC project are presented and the  
188 MAGIC sampler is described in detail. Section 3 then describes the measurement  
189 campaigns and results are presented and discussed. Section 4 provides a  
190 summary and conclusion with some thoughts for the future.

## 191 **2. The MAGIC Idea**

### 192 **2.1 The challenge**

193 In order to understand the role of meteoric smoke particles in the mesosphere  
194 and their impact on that environment their presence must be certified and their  
195 physical characterization (number density, size distribution, shape, composition  
196 etc.) determined. The *in situ* detection of neutral nanometre-size particles is  
197 however very difficult. They are too small for optical detection and their  
198 momentum is not sufficient to produce electrical pulses upon impact. A way to  
199 obtain maximum information about particle properties is by direct collection  
200 followed by detailed laboratory analysis. However, the sounding rocket  
201 approach, which is the only practical method to carry out a sampling experiment  
202 at mesospheric altitudes, is subject to critical limitations imposed by  
203 aerodynamics. As nanometre size particles tend to follow the airflow around the

204 rocket payload structure rather than reaching the detector surface, their  
205 sampling is a substantial experimental challenge and careful aerodynamic design  
206 is of critical importance for smoke particle experiments. The interpretation of  
207 the particle measurements also requires a detailed understanding of the specific  
208 detector response, which is far from trivial. Basic questions are e.g. how  
209 measured particle concentrations and properties are related to the particle  
210 concentrations and properties in the undisturbed atmosphere.

211 Around the turn of the century, significant progress was made in the analysis of  
212 aerodynamic influences on sounding rocket measurements (Gumbel et al., 1998;  
213 Gumbel, 2001) and the fate of atmospheric particles approaching a rocket  
214 detector (Horányi et al., 1999; 2000). Based on these results, the fundamental  
215 concept of the MAGIC instrument design was to minimize the aerodynamic  
216 perturbations by the use of a small sampling probe extending forward of the  
217 rocket payload. By using a collection surface of 3 mm diameter, the sampling  
218 probe dimension is reduced to the order of the molecular mean free path, which  
219 minimizes flow effects on incident particle trajectories in the vicinity of the  
220 probe. In order to characterize the sampling process, Hedin et al. (2007b)  
221 performed simulations of the trajectories of nanometre-sized dust particles  
222 towards the MAGIC detectors with a statistical particle motion model for the  
223 conditions of the first rocket launch at Esrange in January 2005. An important  
224 feature of this model is the Brownian motion of the particles due to thermal  
225 collisions of the gas molecules (Hedin et al., 2007a). Figure 1 shows trajectories  
226 of simulated particles of 0.4, 0.6 and 0.8 nm radii towards the MAGIC sampling  
227 surface at an altitude of 80 km for the conditions of the Esrange 2005 flight (but  
228 with a zero degree angle of attack). The flow is from the left and the grey scale is  
229 the air number density normalized to the unperturbed free-stream conditions. It  
230 can be seen here that even particles as small as 0.4 nm radius will impact on the  
231 sampling surface at this altitude. As a result from this simulation, a detection  
232 efficiency for the MAGIC detector as a function of altitude and particle size is  
233 obtained (Fig. 2). These simulations confirm that particles of radii down to 0.75  
234 nm impact on the sampling surface with an efficiency exceeding 80% over the  
235 entire mesospheric altitude range of interest.

236

## 237 2.2 The MAGIC sampler

238 The MAGIC detector concept was developed in collaboration between the Naval  
239 Research Laboratory (NRL) in Washington D.C. and German and Swedish  
240 scientists (Gumbel et al., 2005) and four MAGIC collection instruments were built  
241 at NRL. In collaboration with the Department of Meteorology at University of  
242 Stockholm (MISU), the first flight of the MAGIC collectors took place on a rocket  
243 launched at Esrange Space Center, Sweden, in January 2005 (the MAGIC  
244 campaign). The second flight was in collaboration with the Virginia Polytechnic  
245 Institute and took place in May 2005 with a launch at Wallops Island, USA. In  
246 September 2006, August 2007 and June/July 2008 MAGIC collectors were  
247 launched as part of the German-Norwegian ECOMA project at Andøya Rocket  
248 Range, Norway. The last flight of a MAGIC collector was on the Swedish PHOCUS  
249 campaign at Esrange, Sweden, in July 2011.

250 As the rocket payload transits the mesosphere, the MAGIC collector sequentially  
251 extends a number of sampling probes at specific altitude windows. On the  
252 exposed face of the probes, transmission electron microscopy (TEM) grids were  
253 mounted to collect particles in a directly analysable form, thus minimizing the  
254 risk of particle loss and contamination. Up to nine sampling pins (of which at  
255 least one is used as reference, i.e. not exposed to the atmosphere) are mounted in  
256 a revolver mechanism (Fig. 3). This pin-revolver mechanism is driven by a worm  
257 gear, which allows sequential positioning of the pins with high precision under  
258 the pin exit hole of the revolver-chamber. Once in position, a chain drive  
259 mechanism is used to extend a piston, which pushes the collection pin upward  
260 through the exit hole in the top of the MAGIC instrument (Figs. 4 and 5). Particles  
261 that impact the TEM grid while extended outside of the MAGIC instrument are  
262 expected to stick by van der Waals forces. After a few seconds the pin is retracted  
263 back into its original position in the pin-revolver. A pair of permanent magnets  
264 provides the necessary coupling of the extension piston to the sampling pin, so  
265 that the sampling pin can be retracted into the revolver. The extension piston  
266 detaches from the magnet when the collection pin is completely back in its  
267 compartment in the revolver. The worm gear then drives the pin-revolving  
268 mechanism so that the next pin can be extended. In this way dust from specific

269 altitude intervals in the mesosphere can be analysed when the TEM grids are  
270 returned to Earth.

271 The pin exit hole is opened by removing a vacuum plug that is used to seal the  
272 exit hole during launch. This plug mechanism is controlled by a rod, which is  
273 extended through the pin-revolver mechanism's axis. This rod is driven by a  
274 lead-screw that lifts the plug out of the exit hole. The plug is then rotated with  
275 the revolver mechanism, until it returns to its original position at the end of the  
276 sampling sequence near the apogee of the flight. At this point the plug is  
277 reinserted to vacuum seal the chamber thus preventing water or other  
278 contaminants from entry into the MAGIC instrument on landing.

279 Nominally the MAGIC collection system is completely self-contained, i.e. it has its  
280 own power supply (rechargeable batteries), microprocessor and requires no  
281 telemetry. A signal is sent from the rocket service module at a pre-set time after  
282 the launch to start the sampling sequence as programmed in the microprocessor.  
283 For the purpose of real time monitoring of the MAGIC instrument during flight,  
284 two signals have been transmitted by telemetry, (1) pressure inside instrument  
285 and (2) status signal indicating when a collection pin is in the extended position.  
286 Monitoring of these two signals during flight and subsequent instrument checks  
287 are performed to confirm that the instrument functioned as expected. After the  
288 ECOMA campaign in 2006, the electronics were remodelled and the internal  
289 power supply was removed. From then on, the MAGIC samplers were powered  
290 from the rocket service module.

### 291 **2.3 Sampling surface**

292 The appropriate choice of collection surface for nanometre-size particles is  
293 crucial. With regard to the anticipated laboratory analysis, the use of carbon film  
294 coated TEM grids as sampling surfaces has been the primary choice. An  
295 important benefit of using TEM grids as sampling surfaces, is that additional post  
296 flight treatment of collected particles, such as separating and moving the  
297 nanometre size particles from the sampling surfaces is not required.

298 Two experimental investigations have been made to test the sticking efficiency of  
299 the TEM grids for nanometre size particles (Reissaus et al., 2006). Using a  
300 molecular-beam apparatus at the University of Jena, Al<sub>2</sub>O<sub>3</sub> and C particles of a

28  
301 few nanometres were produced at speeds of 1 km/s. The laboratory impact  
302 experiments demonstrated that nanoparticles, both as single particles and fractal  
303 agglomerates, do stick on carbon surfaces after high velocity impacts with  
304 moderate efficiency (14%) for Al<sub>2</sub>O<sub>3</sub> and moderate to high efficiency (24–83%)  
305 for C. The higher collection efficiency for C particles may be due to that they  
306 chemically bind to the C on the TEM grids. Unfortunately, the relevance of these  
307 numbers for the mesospheric MAGIC measurements remains unclear as the  
308 overall sticking probabilities determined in the laboratory may be dominated by  
309 large agglomerates of nanometre particles that were formed in the molecular  
310 beam prior to impact on the grids. As an additional finding, the experiments  
311 confirmed that at speeds of the order of 1 km/s the particles do not penetrate the  
312 carbon film on the TEM grid. These experiments were made with a 0° angle of  
313 attack, i.e. the particles impacted the surface with normal incidence. At angles of  
314 attack of 10-20° or larger, which is typical for sounding rocket experiments  
315 without attitude control, the sticking efficiency will be different (most likely  
316 smaller).

317 Other probe materials have been considered during the development of the  
318 measurement concept, most notably aerogel. While sticking probability in the  
319 aerogel matrix is close to unity, the difficulty in removing nanometre particles  
320 from the aerogel for electron microscopy analysis made the choice of this  
321 material not feasible. On 16 November 2012, a student experiment was launched  
322 on a sounding rocket from Esrange Space Center within the REXUS/BEXUS  
323 program with the objective to collect particles in the mesosphere and  
324 stratosphere. The sampling probes contained collection surfaces of three  
325 different types: standard TEM grids, glass fibre filter paper, and silicone gel (Reid  
326 et al., 2013). Results from the analysis of these surfaces are not yet available.

329 In the preferred payload configuration at least two MAGIC collectors are used  
330 where the instruments alternate the sampling pin extension to ensure that there  
331 are no gaps in the sampling procedure. Before flight the instruments are  
332 carefully prepared in a clean room environment. By using specific mounting  
333 tools, care is taken so that the part of the TEM grid used as collection surface is

334 not in direct contact with any other surface. On every flight, each MAGIC  
335 instrument had (at least) one collection pin with a TEM grid that was only to be  
336 used as a reference surface and that was therefore never extended during the  
337 collection sequence. This unexposed reference TEM grid is attached and  
338 removed together with the ordinary TEM grids used in the collection sequence.  
339 Any contamination from the instrument itself or from TEM grid mounting and  
340 removal procedures will thus be detected on this reference grid. Once the  
341 sampling procedure during flight is completed the MAGIC unit closes the vacuum  
342 seal and is kept under the low vacuum acquired during the time of the sampling  
343 operation in the mesosphere. After the recovery of the payload, the MAGIC  
344 instruments are kept under vacuum until the first examination of the TEM grids.  
345 To avoid the use of additional transfer or storage containers before the first  
346 examination of the reference and collection surfaces, the TEM grids can be  
347 removed adjacent to the transmission electron microscope. In this way, once a  
348 grid is removed from the MAGIC instrument, it can be mounted immediately in  
349 the transmission electron microscope.  
350 It is important to note that the small collector dimensions are a decisive  
351 difference between the current approach and efforts to sample NLC particles in  
352 the 1960s [e.g., Hemmenway et al., 1964a; Farlow et al., 1970]. The aerodynamic  
353 conditions for these large earlier collectors a priori prevented a detection of  
354 particles in the nanometre size range. In addition, the smallness of the MAGIC  
355 collection system concept is a precondition for efficiently keeping sampling  
356 surfaces clean and under vacuum.

357

## 358 **2.5 Data analysis**

359 The analysis of the MAGIC smoke samples after recovery is primarily based on  
360 detailed transmission electron microscopy (TEM) studies mainly at the Materials  
361 Science and Technology Division of NRL and, since 2008, at the Electron  
362 Microscopy Centre (EMC) in the Department of Materials and Environmental  
363 Chemistry at Stockholm University. The TEM analysis is intended to provide  
364 particle numbers, sizes and shapes, while the combination of the TEM technique  
365 with energy-filtered imaging and energy-dispersive x-ray spectroscopy (EDS or  
366 EDX) can provide the elemental composition of the sampled particles. Imaging

367 and compositional analysis studies were performed using a JEOL JEM-2200FS  
368 200-kV (NRL) and a JEOL JEM-2100F 200-kV (EMC) field emission scanning TEM  
369 (STEM), with an EDX system and high-angle annular dark-field (HAADF) imaging  
370 capability. The grids were imaged in conventional bright-field and HAADF modes  
371 to determine particle sizes, shapes and number density.

372 Energy filtered images can be obtained by selecting only the transmitted  
373 electrons that interact inelastically with the sample and thus exhibit an energy  
374 loss characteristic of the elements present in the sample. The energy-filter  
375 window can be tuned to a specific elemental edge so that the image intensity  
376 directly reflects the concentration of the chosen element. Advantages with this  
377 technique are that it is sensitive to light elements including C, N and O, and that it  
378 is relatively fast. EDX can then determine the quantitative elemental and  
379 molecular composition. EDX analysis utilizes the characteristic x-ray  
380 fluorescence emission from the sample due to absorption of energetic electrons  
381 to accurately determine the sample composition. Elements as light as boron can  
382 be detected while quantitative results are obtained for carbon and heavier  
383 elements. These measurements are more time intensive than energy-filtered  
384 imaging, but can be used to determine the composition of the particle to less than  
385 0.01 atom %, if appropriate calibration standards are used.

### 386 **3. Results and discussion**

#### 387 **3.1 First flights**

388 There were two flights of MAGIC instruments in 2005. The first took place in the  
389 MAGIC sounding rocket campaign at 04:37 UT (05:37 LT) on January 10 from  
390 Esrange Space Center, Sweden (68°N, 21°E). On this flight three MAGIC collection  
391 instruments were flown along with the Hygrosonde water vapour instrument  
392 (Khaplanov et al., 1996; Lossow et al., 2008) and two charged aerosol detectors  
393 (Gumbel et al., 2005; Amyx et al., 2008). As can be seen in Fig 4, the three MAGIC  
394 instruments were mounted symmetrically around the centrally located  
395 Hygrosonde. Continuous 30 nm carbon film coated Cu TEM grids (Fig. 5a) were  
396 exposed between 59 km and the apogee of 95 km. The second flight took place  
397 on May 17 from Wallops Island, Virginia (38°N, 75°W) as part of the Virginia

398 Tech Student Sounding Rocket Project (VTSRP). One MAGIC collector was flown  
399 on this flight (Fig. 6), which reached an apogee of 98 km. Three pins with ultra  
400 thin 3 nm continuous carbon film on a holey carbon film (or carbon mesh) coated  
401 Cu TEM grids (Fig. 5b) were exposed between 70 and 97 km (in Fig 5b, the holey  
402 carbon film or carbon mesh is the dark grey net supporting the light grey ultra  
403 thin continuous carbon film).

404 Technical issues associated with the collection TEM grids hampered initial  
405 results from the Estringe grids. The 30 nm thick continuous carbon film resulted  
406 in low contrast between the film and the collected particles. Hydrocarbon build  
407 up during TEM analysis reduced the contrast even further, which consequently  
408 made the analysis more difficult. In spite of this, HAADF images show particles in  
409 the 1-10 nm radius size range. Figure 7 shows particles found on the Estringe  
410 grids. Panels a) to d) in Fig. 7 are images of the grids exposed at altitudes  
411 between 86.3 and 94.5 km, where panel a) shows a high-resolution bright-field  
412 image and the other three are HAADF images. Panels a) and b) are images of the  
413 same region. EDX spectra show weak signal from Si. The square patterns with  
414 reduced contrast in panels c) and d) show the effect of the thin film of  
415 hydrocarbons present on the grid. The reference grids do not show any of these  
416 nanometre-sized particles, but their origin is not known. Larger particles were  
417 seen on both exposed (panels e) and g), exposed at 90.3-94.3 and 93.3-94.5 km,  
418 respectively) and reference grids (panels f) and h)) and are likely contamination.  
419 The large particles shown in panels e) and f) contain Ti, Si, Na, K, Ca and Al, while  
420 the particles in panel g) and h) contain Fe, Si, Al, Ca and Cr. The two on board  
421 Colorado dust detectors (CDDs) indicated particles in the altitude range 79 to 85  
422 km (Amyx et al., 2008) which was covered by pins three and four of each of the  
423 three MAGIC samplers, as can be seen in Fig. 8.

424 For the Wallops flight a switch was made to a new type of TEM grid with a  
425 carbon film thickness of only ~3 nm, about ten times thinner than the Estringe  
426 grids. These new TEM grids gave a much-improved contrast, but came with the  
427 disadvantage of the presence of some silica left from the manufacturing process.  
428 All of the TEM grids from 2005 reveal nanometre particles, however, the imaging  
429 contrast is best on the 3 nm thick regions of the Wallops flight grids shown in  
430 Figs. 9 to 11. For presentation purposes of the grey-scale raw HAADF images

431 were converted to colour using the colour gradient tool in Photoshop CS. This  
432 transformation retains the intensity information of the raw images, in which  
433 contrast is directly proportional to variation in sample thickness and depends  
434 inversely on the square of the atomic number density of the sample. Based on the  
435 1% area analysed, several distinct classes of particles types could be identified.  
436 The most common morphologies are clusters, 10 nm to several microns across,  
437 comprised of aggregated particles of 0.5-2 nm in radius (Fig. 9), which in the EDX  
438 spectra appear to be primarily Si and O. The HAADF images show a range of 10-  
439 50% coverage of the grid film with clusters, corresponding to approximately  $10^4$ -  
440  $10^5$  particles  $\mu\text{m}^{-2}$  in the 0.5-2 nm range, and an atmospheric abundance of  $10^6$ -  
441  $10^7$   $\text{cm}^{-3}$ , assuming 100% collection efficiency. The images indicate a sharp drop-  
442 off in abundance for particle  $>2$  nm. However, due to the presence of silica left  
443 from the manufacturing process, it is not possible to show that these particles  
444 were collected during flight.  
445 Other particle morphologies occur at orders of magnitude lower abundance (see  
446 Fig. 10) than the 0.5-2 nm radius particles. These include isolated 2.5-5 nm  
447 radius particles, holes produced by particles that breached the support film,  
448 particle rings, 25-125 nm monolithic particles, and micrometre-sized particles  
449 and aggregates. The isolated 2.5 - 5 nm particles are dense spheres with varying  
450 concentrations of Si, O, Ca, Al, Fe, and S, consistent with material of meteoric  
451 origin. The holes (vertical arrows, Fig. 10), presumably produced by particles  
452 that breached the support film, are 25-75 nm in radius and are rimmed with  
453 material; possibly peeled back carbon film. The particle rings (angled arrow in  
454 Fig. 10, and Fig. 11) have a diffuse circular perimeter that is sometimes studded  
455 with high-density aggregates. Monolithic particles ranging from 25-125 nm in  
456 radius appear to be individual mineral grains, composed e.g. of silicates and  
457 magnesium aluminium oxides, and faceted surfaces consistent with an origin as  
458 matrix materials from incompletely ablated micrometeorites. There are also of  
459 the order of 10 particles per collection grid in the micrometre size range. These  
460 are most likely contamination, as the presence of particles of this size is common  
461 in the terrestrial environment, even in the clean room environment of the  
462 microscope laboratory. However, some of these large particles have

1  
2 463 compositions and morphologies consistent with an origin as meteoroid  
3 464 fragments or interplanetary dust particles (IDPs).

4 465 The unexpectedly diverse morphologies of the collected material present some  
5 466 questions that have not yet been resolved. The different morphologic groups  
6 467 must result from diverse origins and atmospheric processes. The fact that the  
7 468 most abundant particles observed are in the 0.5-1.5 nm size range is generally  
8 469 consistent with expectations (e.g. Hunten et al., 1980; Kalashnikova et al., 2000;  
9 470 Bardeen et al., 2008; Megner et al., 2008b), i.e., an exponentially decreasing  
10 471 particle abundance with increasing size. However, the absolute abundance  
11 472 observed ( $>10^6$  particles  $\text{cm}^{-3}$ ) is greater than predicted by the atmospheric  
12 473 models by one or more orders of magnitude. The clustering of the particles into  
13 474 what appears to be porous clusters, or fluffy aggregates, was not considered in  
14 475 the above models (e.g. Hunten et al., 1980; Kalashnikova et al., 2000; Bardeen et  
15 476 al., 2008; Megner et al., 2008b). It is unclear what the high surface area of the  
16 477 fluffy aggregates will do to their aerodynamic and chemical properties, e.g.,  
17 478 settling times and surface reactivity, as this will depend on the mass of the three  
18 479 dimensional particle and its surface area. It is possible that the clustering into  
19 480 fluffy aggregates occurred on the sampling grids rather than being created in the  
20 481 atmosphere.

21 482 The less abundant particle morphologies require separate explanation. The  
22 483 spherical 2.5-5 nm radius particles could represent the upper end of the size  
23 484 distribution of individual condensates of ambient ablated meteoritic materials.  
24 485 Their larger size causes a faster settling rate and less time for incorporation into  
25 486 aggregates, which may explain their isolated occurrence. The 75-150 nm  
26 487 diameter holes in the 3-nm thick carbon support films may be produced by  
27 488 dense particles rather than fluffy aggregates. These particles are possibly the  
28 489 same type of particles as the observed 25-125 nm dense monoliths. The material  
29 490 in the rims around the holes could be small grains adhered to the surface of the  
30 491 monoliths that were collected on the film as the monoliths breached the film.  
31 492 Alternatively, the material in the rims could result from deformation of the  
32 493 carbon support film at the breach. The holes are observed on the 76.7-93.5 km  
33 494 and 94.5-97.0 km Wallops collection grids. The rings (see Fig. 11) appear to  
34 495 result from the evaporation of a liquid. During evaporation, the surface tension

33  
496 of the liquid concentrated inclusions of sub-nm to 1.5 nm particles at the  
497 perimeter, producing the diffuse ring. This phenomenon is commonly observed  
498 during TEM analysis of solvent-dispersed synthetic nanoparticles. In the present  
499 case, the source of the liquid is not obvious; melting of a solid particle upon  
500 impact or upon return of the rocket to Earth are possibilities. No residue was  
501 found on the TEM grid that would readily allow the determination of the  
502 composition of the incident particle. Water ice particles are considered very  
503 unlikely as atmospheric temperatures at the collection altitudes are well above  
504 the ice sublimation point. In the cases for which large particulate agglomerates  
505 are observed at the perimeter, it appears most likely that these agglomerates  
506 were deposited by the incident particle as it liquefied, since adjacent regions of  
507 the support film do not contain particles of this size.

508 It must be remembered that observations reported here stem from only a limited  
509 1% study of the returned data. When additional studies were to be performed  
510 after some time on the Wallops grids and lower altitude Esrange grids, the TEM  
511 carbon film had broken in many places during the storage and further analysis  
512 was not possible.

513

### 514 **3.2 ECOMA**

515 In 2006, 2007 and 2008, MAGIC was launched within the ECOMA program  
516 (ECOMA = Existence and charge state of MSPs in the middle atmosphere) from  
517 the North-Norwegian Andøya Rocket Range (69°N, 16°E). The ECOMA project  
518 was an international research program led by the Leibniz-Institute of  
519 Atmospheric Physics (IAP) in Germany and the Norwegian Defence Research  
520 Establishment (FFI) in Norway and brought together scientists from Germany,  
521 Norway, Sweden, Austria, and in 2008 also from the USA. The general objective  
522 was the study of MSPs and their relationship to ionospheric processes  
523 (Strelnikova et al., 2009; Rapp et al., 2010, 2012).

524 The main instrument on board the payloads was the ECOMA detector from IAP; a  
525 classical Faraday cup detector combined with a Xenon flash-lamp for the active  
526 photo-ionization/photo-detachment of MSPs and the subsequent detection of  
527 resulting photoelectrons (Rapp and Strelnikova, 2009). During all three  
528 campaigns, *in situ* measurements of neutral density, temperature and turbulence

529 were provided by IAP, and ionization conditions were studied in terms of  
530 ionospheric composition and turbulence by the Technical University Graz,  
531 Austria, and FFI. Figure 12 shows the front deck configuration (under the  
532 nosecone) of the ECOMA payloads. Both the 2007 and 2008 campaigns were  
533 conducted during the NLC season and the presence of ice particles was  
534 monitored by on-board NLC photometers from MISU. In 2008 additional  
535 detectors for charged particles were flown by Dartmouth College, USA, and the  
536 University of Tromsø, Norway. The rocket-borne measurements were  
537 complemented by the comprehensive ground-based instrumentation at Andøya  
538 Rocket Range, in particular the ALOMAR lidars and radars, as well as the EISCAT  
539 radar facility.

540

### 541 **3.2.1 ECOMA 2006 Campaign**

542 The 2006 ECOMA campaign was planned to feature three launches with two  
543 MAGIC detectors on each payload (Fig. 12a-b). The four MAGIC instruments were  
544 jointly prepared by NRL and MISU. In an attempt to clean the grids from Si and  
545 other contamination in the carbon film, the grids were treated at NRL with a  
546 chemical etching using a gas mixture of  $\text{CF}_4$  and Ar under plasma cleaning  
547 conditions. After this the grids were oxidized by plasma cleaning in an  
548 atmosphere of  $\text{O}_2$  and Ar. The first payload and set of two MAGIC detectors were  
549 to be refurbished and launched a second time as launch number three. The  
550 ECOMA-01 payload was launched on September 8, 2006 at 22:17:00 UT (LT = UT  
551 + 2 h) and reached an apogee of 130.6 km. All instruments performed nominally  
552 and the two on-board MAGIC instruments performed the sampling sequence  
553 with 7 pins each covering more or less the entire altitude region from 68 to 116  
554 km. The ECOMA detector measured photoelectrons from the photo-  
555 ionization/photo-detachment of MSPs from 80 km altitude on the ascent  
556 (Strelnikova et al., 2009). The TEM grids used on this flight were the same type of  
557 TEM grids that was used on the earlier MAGIC campaign at ESRANGE (continuous  
558 30 nm carbon film on a 200 lines/inch Cu mesh). The chemical etching of the  
559 carbon film before flight also made the carbon film thinner thus improving the  
560 contrast and making it possible to see smaller particles.

16  
17  
561 The ECOMA-02 payload was launched nine days later on September 17, 2006 at  
562 21:06:45 UT and reached an apogee of 130.3 km. The two on-board MAGIC  
563 instruments sampled the atmosphere from 68 to 120 km altitude using the same  
564 type of grids as was used on the Wallops Island launch in 2005 (ultra thin carbon  
565 film on a holey carbon support film and Cu mesh). Unfortunately, this payload  
566 was lost to the bottom of the sea due to a malfunction of the payload recovery  
567 system, and consequently two MAGIC collectors were lost and analysis of these  
568 grids was not possible. This malfunction led to the premature termination of the  
569 2006 campaign to investigate the failure and hence, no third launch was carried  
570 out.

41  
42  
571 The ECOMA-01 MAGIC sampling grids all suffered from heavy contamination. In  
572 addition to the film-like hydrocarbon contamination that was seen on the grids  
573 from the 2005 MAGIC campaign there were hydrocarbon blobs: dark, opaque,  
574 roundish blobs and lighter, irregularly shaped blobs with central dark spot (Fig.  
575 13a-b). Also “snow flake” shaped hydrocarbon contamination was seen (Fig.  
576 13c). The EDX data of the hydrocarbon contamination showed abundance of C  
577 and F which is consistent with the lubrication used on the O-rings in the MAGIC  
578 housing. So the source of the thick hydrocarbon contamination was most likely  
579 vaporising of the O-ring lubricant and melting of the O-rings near the pin exit  
580 hole during re-entry into the denser atmosphere. On ECOMA-01 the MAGIC  
581 samplers were mounted in a less protected manner than in the two flights in  
582 2005 and, hence, were more susceptible to air frictional heating during re-entry  
583 (see Fig. 12a-b).

64  
65  
584 Although the hydrocarbon contamination made EDX difficult, abundant spherical  
585 particles with radii in the 0.5-5 nm size range were also found on the ECOMA-01  
586 MAGIC grids. The most abundant type was Fe-rich particles composed of Fe and  
587 Cr with some Ni and Mo. Cr, Ni and Mo are common components of stainless  
588 steel, but Mo has a very low abundance in meteoritic material. Also the Cr  
589 content (~10-20%) was much higher than what is found in chondrites, or  
590 expected in meteoric smoke particles, but consistent with stainless steel. This  
591 indicates that these particles are stainless steel and thus most likely  
592 contamination. As opposed to the hydrocarbon contamination, the source of the  
593 stainless steel particles has never been identified. Several EDX measurements

594 were performed of the composition of suspect parts used in the MAGIC sampling  
595 unit and the ECOMA detector, but none of the parts contained Mo. The  
596 conclusion was that the stainless steel particles do not come from the MAGIC  
597 units, nor from the ECOMA detector, but must come from somewhere on the  
598 rocket. A possible explanation was the presence of nanosize steel spheres in a  
599 lubricant applied in the payload's nosecone separation system. It is also possible  
600 that the rocket motor passed the payload after separation due to aerodynamic  
601 effects or afterburning. This has happened in some cases in the past, which  
602 means that the motor ends up upstream of the payload and all kinds of debris  
603 will reach the payload. The first MAGIC grid was exposed between 68 and 73 km  
604 while the motor was separated later, at an altitude of 75 km. The second and  
605 third TEM grids of that same MAGIC instrument was exposed after the  
606 separation (between altitudes 78 and 86 km, and 89 and 93 km, respectively)  
607 show at least an order of magnitude more particles per unit area than what is  
608 seen on the first grid (see Fig. 14). The second MAGIC instrument exposed its  
609 first TEM grid between 78 and 82 km and has the same amount of particles as  
610 the subsequent second and third grids. This is consistent with the idea that the  
611 contamination could come from the motor. However, even though the grid  
612 exposed before motor separation shows much less particles, there were still  
613 stainless steel particles with Mo on this grid. Also the reference grids show  
614 abundant nanometre sized stainless steel particles containing Mo. The top ring of  
615 the front deck of the ECOMA payload (onto which the nosecone is mounted, see  
616 Fig. 12a) is made of stainless steel that does contain Mo. It is however not known  
617 what process would produce nanometre-sized particles from this surface. If the  
618 particles were exclusively from the atmosphere, and assuming a 100% sticking  
619 efficiency, the amount of particles on the first, second and third grids of the  
620 second MAGIC sampler would correspond to an atmospheric number density of  
621  $\sim 1.5 \times 10^4 \text{ cm}^{-3}$  for particles of radius 1 nm and larger (a factor of about two  
622 orders of magnitude smaller than for the Wallops Island flight). The second most  
623 abundant type of particles was larger in size ( $\sim 50\text{-}100 \text{ nm}$  radii) and contained  
624 Ca and S with K and/or Na (or possibly Zn). The source of these is not known. No  
625 signs were found of ring structures or holes in the film similar to what was seen  
626 on the Wallops Island flight.

627 After the 2006 ECOMA campaign, O-rings and lubricant were changed to more  
628 heat resistant types. Also an extension to the MAGIC instrument was added to  
629 protect the pin exit hole and the volume around it from the possible airflow  
630 through the ECOMA detector (see Fig. 12c). These extensions also served as heat  
631 shields of the upper MAGIC housing during re-entry.

632

### 633 **3.2.2 ECOMA 2007 Campaign**

634 Similar to the 2006 ECOMA campaign, the 2007 campaign was planned to feature  
635 three launches with two MAGIC detectors on each payload. On August 3, 2007 at  
636 23:22:00 UT the ECOMA-03 payload was launched and reached an apogee of 126  
637 km. Unfortunately, also this payload was lost to the bottom of the sea due to a  
638 malfunction of the payload recovery system. The decision was made to terminate  
639 the campaign prematurely to investigate the malfunction, and return in 2008.  
640 Now all four MAGIC collectors originally manufactured at NRL had been lost.  
641 Thanks to the efforts of NRL, MISU and DLR Moraba, two new MAGIC samplers  
642 could be built mainly from spare parts.

643

### 644 **3.2.3 ECOMA 2008 Campaign**

645 MAGIC particle samplers were flown on three payloads during the ECOMA  
646 campaign in June/July 2008. One MAGIC instrument for each rocket payload was  
647 jointly prepared by NRL and Stockholm University, again with the first payload  
648 and MAGIC collector to be refurbished and launched a second time. The three  
649 launches (ECOMA-04, -05 and -06) took place on June 30 at 13:22 UT, July 7 at  
650 21:24 UT, and July 12 at 10:46 UT, respectively (LT = UT + 2h). The payloads  
651 performed nominally and were successfully recovered by boat after the water  
652 landing. The scientific conditions for all flights were interesting. All three went  
653 into NLC ice particle layers as confirmed by the on-board photometers from  
654 Stockholm University. For the first and third flights, sampling was performed  
655 below (one grid), within (one grid) and above (two grids) the NLC on each flight.  
656 On the second flight, the opening of the extension of the first pin was delayed for  
657 some unknown reason and the sampling started inside the NLC. Two additional  
658 pins in each MAGIC collector were prepared with grids and used as reference (i.e.  
659 not extended). Strong polar mesosphere summer echoes (PMSE) were present

65

660 during the first and third flight and completely absent during the second. The  
661 ECOMA detector reported the presence of particles above 77 km for ECOMA-04,  
662 above 81 km for ECOMA-05, and above 70 km for ECOMA-06 (Rapp et al., 2010).  
663 Above 90-95 km the ECOMA photoelectron measurement is most likely  
664 contaminated by photoelectrons from the photo-ionisation of NO (Rapp and  
665 Strelnikova, 2009; Rapp et al., 2012).

666 The TEM grids used for these flights were the 30 nm continuous carbon film on  
667 Cu support grids also used earlier. Also this time the grids were pre-treated at  
668 NRL to reduce Si and other contaminants and to improve the contrast by making  
669 them thinner. The grids were then characterised at Stockholm University before  
670 launch to determine the quality of the carbon film, the number of particles and  
671 their chemical composition. This analysis was made in the four central squares of  
672 each grid and in one grid that is covered by the Cu masks (Fig. 15a). The grid  
673 square covered by the Cu mask was used as an on-grid reference area. This  
674 characterisation was then used to rank the quality of the TEM grids and to  
675 determine which ones should be mounted in the MAGIC collector. The same  
676 analysis was then also made after the flights. The set of six TEM grids from the  
677 ECOMA-04 flight was analysed at Stockholm University, while the two sets from  
678 the ECOMA-05 and -06 flights were directly shipped back to NRL for analysis.

679 During the pre-flight analysis, the only elements that could be observed in the  
680 carbon film above the detection limit were C (film and some flakes), O, F, Si  
681 (particles smaller than 5 nm) and Cu. F and possibly O originate from the plasma  
682 cleaning process, while Si is still some contamination left from the grid  
683 manufacturing process also after the plasma cleaning. The Cu signal originates  
684 from the fluorescence of the surrounding support grid and possibly from  
685 deposition onto the film by the plasma cleaning process. In STEM-HAADF mode  
686 small particles could be observed that by spot measurements give EDX spectra  
687 that locally indicate high concentrations of the elements Na, Al, Mg, Si, Cr, Mn, Fe  
688 and Ni. After the launch the same characterisation was performed on the  
689 ECOMA-04 grids at Stockholm University. Table 1 summarizes the elemental  
690 composition analysis of the TEM grids before and after launch. The conclusions  
691 from this characterisation are that the grids survived almost intact with no  
692 serious damage to the carbon film, and that the overall chemical composition of

693 the carbon film was the same, with the exception of an increase of Cu and a  
694 reduction of O (highlighted with red squares in Table 1). There were no signs of  
695 hydrocarbon contamination or stainless steel particles on any of the grids.  
696 Hence, the change of O-ring lubricant and the addition of the extension as a  
697 protection and heat shield after the ECOMA-01 launch helped. However, no  
698 flight-sampled nanometre-sized particles could be identified.

699 The increase of Cu on the carbon film is significant, and it increases with altitude.  
700 However, the highest concentrations are observed on the reference grids that  
701 were not exposed. The increase in Cu content is seen as an addition of small sub-  
702 nanometre to nanometre particles onto the carbon film. Except on the first grid,  
703 the oxygen content of the carbon film decreases significantly with exposure  
704 altitude, including the reference grids. The concentrations of the other elements  
705 were more or less constant. A large number of STEM-HAADF images of the  
706 carbon film were recorded with the aim to calculate the number of collected  
707 particles and their sizes. The general observation was that with increasing Cu  
708 content the number of particles also increased. This causes a problem in  
709 identifying smoke particles by EDX as the noise from the Cu contamination  
710 drains the signal from the other elements.

711 On the grid that was exposed when the payload passed through the NLC layer,  
712 large spherical agglomerates (radii  $\sim 0.5 - 0.8 \mu\text{m}$ ) were found after the flight.  
713 Energy filtered imaging (Fig. 16) shows that they contain Na, S, Si and O with  
714 some Cl, K, Ca, Mg, Cr, Mn and Fe in both the centre and outer parts of the  
715 agglomerated material. The number of such agglomerates was estimated to  
716 about four in each of the four central squares. Similar agglomerates were,  
717 however, also found on the reference square under the Cu mask (Fig. 17a). The  
718 Cu mask was not mounted completely flush to the TEM grid, so there is a  
719 possibility for particles to enter in the space between them and end up on a grid  
720 square under the mask. More careful studies showed appearance of this type of  
721 particles also on the two unexposed reference grids (Fig. 17b-c). It is possible  
722 that, even if they were not observed before flight, they could have been there  
723 from the beginning. These agglomerates are very similar in shape and size to the  
724 patterns seen on the surfaces exposed to NLC in the 1960s (Hemenway et al.,  
725 1964b; Skrivanek and Soberman, 1964). If these agglomerates are NLC particles

726 from the 1 km thick ice layer as seen by the on-board NLC photometer, the  
727 number density derived from the second grid is  $0.5 \text{ cm}^{-3}$  (if the sticking efficiency  
728 is 100 %). This is a factor of about two orders of magnitude smaller than for  
729 typical NLCs (e.g. von Cossart et al., 1999; Baumgarten et al., 2008).

730 The grids from ECOMA-05 and -06 that were shipped to NRL were not in the  
731 same good condition when they arrived as the grids that were analysed at  
732 Stockholm University. There were many places where the carbon film had  
733 ruptured, and this most likely happened during transport. An attempt was made  
734 to calculate the number of nanometre sized particles and their size distribution  
735 on the ECOMA-06 grids. The results are summarised in Table 2 and from this it  
736 can be seen that the particles on all grids are almost identical, with similar mean  
737 radius and spread. The atmospheric particle number densities calculated  
738 assuming 100% sticking efficiency are several orders of magnitude higher than  
739 what is expected from models for particles of this size and for polar summer  
740 conditions (Megner et al., 2008a). This all suggests that these particles are in fact  
741 contamination.

742

### 743 3.3 PHOCUS

744 The last flight of a MAGIC sampler was on the PHOCUS sounding rocket launched  
745 from Esrange Space Centre, Sweden, on July 21, 2011, at 07:00:53 UTC into a  
746 strong NLC. PHOCUS, which is an acronym for Particles, Hydrogen and Oxygen  
747 Chemistry in the Upper Summer mesosphere, was a Swedish sounding rocket  
748 project led by MISU with contributions from Norway, Germany, Austria and the  
749 USA (Gumbel et al., 2013; Havnes et al., 2013; Hedin et al., 2013; Sternovsky et  
750 al., 2013). In this context, particle species comprise ice particles, smoke particles  
751 of meteoric origin, and possibly other background particles formed by  
752 conversion from trace gases. Important questions concerned both the properties  
753 of particle layers and their interaction with various phenomena in the  
754 mesosphere and lower thermosphere. This includes the relationship between  
755 smoke and ice, ice particle nucleation and evolution, and the possible influence of  
756 these particle species on chemistry. Both the German/Norwegian ECOMA project  
757 and PHOCUS aimed at the characterization of smoke and ice particles and their  
758 interactions. While ECOMA concentrated on interactions with ionospheric

759 processes, PHOCUS concentrated on interactions with neutral O<sub>x</sub>/HO<sub>x</sub> chemistry.  
760 The configuration of the front deck with the nosecone removed is shown in Fig.  
761 18. The rocket measurements were complemented by ground-based  
762 instrumentation at Esrange (the ESRAD MST radar and the Esrange lidar), the  
763 EISCAT facility, the MORRO radar near Tromsø, and the MAARSY radar on  
764 Andøya.

765 One MAGIC sampler was prepared at Stockholm University with ultra thin  
766 carbon film on a holey carbon support film and 400 lines/inch Cu mesh. This  
767 time, only one grid was exposed in the altitude region where MSPs and ice  
768 particles are expected to be present. In addition, seven reference pins of two  
769 different types were prepared. Four pins were prepared in the same way as the  
770 exposed grid, i.e. a TEM grid with a Cu mask of 1 mm diameter aperture, while  
771 three pins were prepared with a Cu cap that completely covered the TEM grid  
772 (see Fig. 19). If the completely covered grids were to show particles after flight  
773 they would be contamination deposited on the grids in the clean room when  
774 mounting or removing the grids, or when being transferred to the TEM. As with  
775 the ECOMA 2008 campaign, a detailed characterization of the grids was made  
776 before flight (in the five squares as shown in Fig. 15a). No plasma cleaning was  
777 done this time. The characterization showed that these grids were very much  
778 cleaner compared to grids flown in earlier campaigns. The pre-flight EDX spectra  
779 of the grids showed C from the carbon film, Cu from the copper support mesh  
780 and a small Si signal from the detector itself, but no signal from the transition  
781 metals Cr, Mn, Fe or Ni that were seen earlier. A small amount of NaCl particles  
782 were seen which would be readily identified after flight as belonging to the grid  
783 from the beginning.

784 At the time of launch the Esrange lidar indicated the presence of a strong NLC  
785 layer and the Esrange MST radar, which had been monitoring the development of  
786 the PMSE during the morning hours, showed a narrowing and lowering of the  
787 PMSE layer indicating an aged ice layer with large particles. During flight the  
788 three on board NLC photometers detected a strong but thin NLC layer between  
789 81 and 82 km altitude (Gumbel et al., 2013). The three different detectors for  
790 charged particles report a narrow structured layer between 81 and 82 km  
791 altitude (Havnes et al., 2013; Sternovsky et al., 2013). This does not mean that

1  
2 792 there were no particles below or above this layer, but that they were too small to  
3 793 reach the detectors due to aerodynamics.

4 794 The TEM analysis after the flight showed no new particles on either of the two  
5 795 types of reference grids, i.e. no contamination of the grids occurred during  
6 796 handling or during flight. Detailed analysis of the exposed grid reveals no new  
7 797 particles either. This grid was exposed between 77.3 and 91 km altitude, i.e. from  
8 798 well below until high above the NLC ice particle layer at 81-82 km detected by  
9 799 the three charge impact detectors and the NLC photometers. Typical NLC particle  
10 800 number densities are around  $100 \text{ cm}^{-3}$  (e.g. von Cossart et al., 1999; Baumgarten  
11 801 et al., 2008) which means that, after passing through the 1 km NLC layer, there  
12 802 would be 0.1 ice particle impacts per square micrometre, or 160 impacts in each  
13 803 Cu grid square on the exposed TEM grid. The charged particle detectors estimate  
14 804 that there were one to two orders of magnitude more particles in the NLC layer,  
15 805 which means there would have been 1-10 particle impacts per square  
16 806 micrometre on the grid. The TEM investigations of the exposed grid show no  
17 807 evidence of particle impact or contamination (no sub-nanometre or nanometre  
18 808 sized particles, no holes in the C film, no monoliths or 25-200 nm radius  
19 809 particles, no ring-like structures or agglomerated particles) and no hydrocarbon  
20 810 contamination that were seen on earlier flights. Since particles were present in  
21 811 the altitude region sampled, as shown by the charge impact detectors, and must  
22 812 have impacted on the sampling grid, it must be concluded that the particles have  
23 813 bounced off and did not stick to the surface. For this flight it has thus been shown  
24 814 that no contamination was introduced during handling of the grids or during  
25 815 flight and that the sticking efficiencies for meteoric smoke and ice particles are  
26 816 most likely very small.

#### 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 817 **4. Summary and conclusion**

50  
51 818 The MAGIC meteoric smoke particle sampler was developed and built to allow  
52 819 for the first time MSPs to be sampled in the upper mesosphere and lower  
53 820 thermosphere and returned to the ground for detailed laboratory investigations.  
54 821 MAGIC samplers have been flown and successfully recovered on seven payloads.  
55 822 After all flights, except for PHOCUS, particles of different sizes, shapes and

823 composition were found. Particles of sizes and elemental composition similar to  
824 what can be expected for MSPs were found but due to challenges with large  
825 amounts of different types of contamination (particles and hydrocarbon film and  
826 drops) and large uncertainties in the sticking efficiency of the particles on the  
827 sampling surfaces, no conclusive results have been obtained. Table 3 summarises  
828 all successfully recovered flights and gives approximate sampling altitudes for  
829 each grid. The 2005 and 2006 launch campaigns were conducted during times  
830 when mesospheric ice particles were absent, i.e. outside polar summer  
831 conditions, while the 2008 and 2011 campaigns were conducted during peak  
832 NLC season with confirmed presence of ice particles. Models of the distribution  
833 of MSPs show that the particle concentration should be very much reduced in the  
834 polar summer mesosphere due to the general circulation of the atmosphere (e.g.  
835 Megner et al., 2008a). This would suggest that much more nanometre sized  
836 particles should be found on the grids from the non-summer flights compared to  
837 the summer flights. This is also what is seen, i.e. more particles on the grids from  
838 the non-summer flights. However, the amounts of particles on the non-summer  
839 flights are much too high (several orders of magnitude), even when a sticking  
840 efficiency of the particles on the carbon film of 100% is assumed, suggesting that  
841 a majority of them are contamination. The ECOMA-01 grids show heavy  
842 contamination from hydrocarbons and stainless steel particles and it is difficult  
843 to draw conclusions about possible other particles as they drown in the signal  
844 from the contamination. For the two summer campaigns no in-flight sampled  
845 nanometre sized particles were discovered on the grids. The ECOMA-05 and -06  
846 grids were damaged during transport back to NRL, and particles found on the  
847 ECOMA-06 grids are most likely contamination. Analysis of the ECOMA-04 grids  
848 shows the presence of large spherical agglomerates ( $\sim 0.5 - 0.8 \mu\text{m}$  radii) on the  
849 grid that was exposed during passage of the NLC layer, but also on the two  
850 reference grids (Figs 16 and 17). Such agglomerates have not been seen on any  
851 of the other flights of the MAGIC samplers, but show similarities to attempts to  
852 sample NLC particles in the 1960's. On the Wallops Island flight, holes in the  
853 ultra-thin C film (Fig. 10) and ring-like structures were seen (Fig. 11) that have  
854 not been seen on any of the other flights. Analysis of the PHOCUS grid shows no  
855 evidence of in-flight sampled particles of any size, neither on the exposed grid

1  
2  
3  
4  
5  
6  
7  
8  
856 nor on any of the reference grids. This suggests that the sticking efficiencies for  
857 both pure MSPs and MSPs contained in ice particles are very small. The lack of  
858 in-flight sampled nanometre sized particles on the summer flights also suggests  
859 that the improvements made to minimize the contamination had an effect and  
860 that the sampling process and handling of the samples has become cleaner.

861 As stressed earlier, the sticking efficiency for MSPs (pure and contained in ice  
862 particles) on the sampling surface is a major uncertainty. A recent study was  
863 made with C and Al<sub>2</sub>O<sub>3</sub> particles impacting on surfaces of C, Au and grease  
864 (Reissaus et al., 2006). From this, a sticking efficiency for Al<sub>2</sub>O<sub>3</sub> particles on C of  
865 ~14% was found (relative to a grease surface, for which a sticking efficiency of  
866 100% for Al<sub>2</sub>O<sub>3</sub> particles was assumed). The handling of such small particles is  
867 very difficult and the associated uncertainties of the properties of the impacting  
868 particles are large. It is also difficult to say how applicable this study is to actual  
869 rocket-borne sampling in the mesosphere. Studies have been made earlier on the  
870 capture and rebound of small particles upon impact with surfaces (e.g. Dahneke,  
871 1971; Tsai et al., 1990), although at lower velocities, showing significant particle  
872 bounce.

65  
873 The *in situ* sampling of MSPs remains an extremely challenging endeavour.  
874 Detailed studies are needed with different sampling surface types and a reliable  
875 source of MSP analogues under conditions relevant for mesospheric sampling  
876 from a sounding rocket (e.g. different velocities and angles of attack). Similar  
877 studies should be performed for dirty ice particles in the 30 to 100 nm radius  
878 size range. This is not only important for future instruments, but also to validate  
879 the MAGIC results. To collect as much MSPs as possible and keep the instrument  
880 simple, a single pin with a TEM grid should be exposed throughout the  
881 mesospheric dust layer, as was attempted on the PHOCUS payload. Then, after  
882 that successful sampling of MSPs has been demonstrated, the altitude  
883 distribution should be investigated. The rocket flight must be designed to  
884 maximize the probability of collecting MSPs. To minimize the risk of the particles  
885 bouncing off the surface, the apogee should be within the layer so that the  
886 sampling surface has a low relative velocity with respect to the dust and the  
887 payload should preferably be attitude controlled to maintain a small angle of  
888 attack. Different sampling surface materials should be investigated carefully. The

889 use of a soft material as the collection surface, such as e.g. aerogel, was  
890 considered at the early stages of the MAGIC design work. It was however felt at  
891 that time that the granularity of the aerogel was too coarse for the nanometre  
892 sized MSPs and that the preparation of such a sample for the TEM following a  
893 flight would introduce contaminants that would be difficult to distinguish from  
894 the MSPs. Therefore it was decided to use the cleaner solution of the TEM grids.  
895 The MAGIC project was originally designed during a time when very little was  
896 known quantitatively on smoke particles in the mesosphere. Since then, major  
897 progress has been achieved by remote sensing (Hervig et al., 2009; 2012),  
898 rocket-borne measurements of charged particles (Rapp et al., 2010; 2012), radar  
899 studies (Strelnikova et al., 2007; Rapp et al., 2007), and numerical modelling  
900 (Megner et al., 2008b; Bardeen et al., 2008). Nevertheless, direct *in situ* sampling  
901 of MSPs is still highly desirable. Only direct *in situ* sampling can presumably  
902 provide final evidence about particle composition, size and shape. Knowledge  
903 about these microphysical properties continues to be a key to understanding  
904 both the evolution and the interaction of meteoric material in the mesosphere.

905  
906 **Acknowledgements:** We acknowledge Robert R. Meier for the original idea to  
907 measure meteoric smoke particles. MAGIC was a NASA project funded under  
908 Grant No. NDPR S-06215-G. The MAGIC and PHOCUS sounding rocket projects  
909 were funded by the Swedish National Space Board. The ECOMA project was  
910 sponsored by the German Aerospace Center (DLR), and the Norwegian Space  
911 Center and the Research Council of Norway supported the Norwegian  
912 contribution. We thank for the opportunity to participate in the VTSRP and  
913 ECOMA projects with MAGIC MSP samplers, and acknowledge the excellent  
914 support of SSC, Esrange Space Center, Wallops Flight Facility, Andøya Rocket  
915 Range, the Norwegian Defence Research Establishment and DLR-Mobile Rocket  
916 Base (Moraba). The new electron microscopy facility at Stockholm University  
917 was made possible by the support from the Knut and Alice Wallenberg  
918 foundation.

1332 **Figure captions**

1333

1334 **Figure 1.** Simulated particle trajectories of (a) 0.4, (b) 0.6 and (c) 0.8 nm radius  
1335 particles around the MAGIC sampling surface at 80 km altitude (from Hedin et  
1336 al., 2007b). The grey scale is the air number density normalized to the  
1337 unperturbed free-stream conditions.

1338

1339 **Figure 2.** The effective relative cross section of the MAGIC sampling surface for  
1340 (a) various particle sizes as a function of altitude and (b) various altitudes as a  
1341 function of particle size (from Hedin et al., 2007b).

1342

1343 **Figure 3. (a)** Instrument sketch of the collection mechanism inside the MAGIC  
1344 instrument. **(b)** Close-up photo of the revolver with 9 collection pins. **(c)** The  
1345 MAGIC collector unit with extended sampling pin. The cylindrical section houses  
1346 the revolver with eight collection pins and one reference pin. The lower  
1347 rectangular section houses the collection and extension mechanism. The  
1348 included 50 cm scale indicates the size of the MAGIC instrument. **(d)** Close-up  
1349 photo of the 3 mm diameter TEM grid mounted with Cu cap on top of an  
1350 extended sampling pin.

1351

1352 **Figure 4.** The top of the MAGIC sounding rocket payload launched from Esrange  
1353 in January 2005. A sampling pin is extended from one of the three MAGIC  
1354 sampling units surrounding the Hygrosonde instrument (Khaplanov et al., 1996;  
1355 Lossow et al, 2008a) in the centre.

1356

1357 **Figure 5. a)** The centre of the 30 nm thick continuous carbon film (grey) on 200  
1358 lines/ inch copper mesh (black) TEM grid used in the Esrange flight. b) Centre of  
1359 the 3 nm ultra thin carbon film (light grey) on holey carbon film (or carbon mesh,  
1360 dark grey net) and 400 lines/inch copper mesh (black) TEM grid used in the  
1361 Wallops Island flight.

1362

1363 **Figure 6.** A MAGIC sampling pin extended through the forward bulkhead in front  
1364 of the VTSRP payload launched at Wallops Island in 2005.

1365

1  
2 1366 **Figure 7. a)** High-resolution bright-field TEM image of the grid exposed between  
3 1367 93.3 and 94.5 km, while **b)** is a high-angle annular dark-field (HAADF) image of  
4 1368 that same area, showing particles in the 1-5 nm radius size range. Panels **c)** and  
5 1369 **d)** are HAADF images of the collection grid exposed between 86.3 and 89.3 km  
6 1370 showing particles in the 2-10 nm radius size range. The square patterns show  
7 1371 the effect of the thin film of hydrocarbon present on the grid. Panel **e)** shows a  
8 1372 large particle from the grid exposed between 90.3 and 94.3 km containing Ti, Si,  
9 1373 Na, K, Ca, and Al and panel **f)** shows a particle with similar composition and  
10 1374 morphology found on one of the unexposed reference grids. Panel **g)** shows a  
11 1375 particle found on the grid exposed between 93.3 and 94.5 km and contain Fe, Si  
12 1376 Al, Ca and Cr, while panel **h)** show a particle of similar composition and  
13 1377 morphology found on one of the reference grids.

1378

1379 **Figure 8.** Measurement of mesospheric particles by the Colorado dust detectors  
1380 (CDDs) on board the MAGIC sounding rocket (Amyx et al., 2008). The vertical  
1381 lines indicate where MAGIC detectors sampled the atmosphere in the altitude  
1382 range where the CDDs indicated presence of particles (e.g. M1G3 indicates grid 3  
1383 on MAGIC sampler 1 and M3G4 indicates grid 4 on MAGIC sampler 3 etc.).

1384

1385 **Figure 9.** High-angle annular dark-field (HAADF) image of atmospheric  
1386 nanoparticles. The colour values in the image represent scattering intensity,  
1387 which is a function of material thickness and composition. The yellow area is a  
1388 30 nm thick region of the supporting holey carbon collection film; the red areas  
1389 are particles 0.5 to 2 nm in radius; and the blue areas are bare regions of the 3  
1390 nm ultra thin portions of collection film. The particles form what appears to be a  
1391 fractal aggregate, which varies in density. The large red spot is a densely packed  
1392 region of the 0.5 to 2 nm particles.

1393

1394 **Figure 10.** High-angle annular dark-field (HAADF) image of representative  
1395 particle morphologies. As in Fig. 9, the 30 nm thick holey carbon support mesh  
1396 appears yellow, and bare regions of the ultra thin 3 nm carbon film are blue.  
1397 Particles range from red to yellow in appearance, depending on thickness and

1398 compositions. Particle clusters are distributed across the film. The two angle  
1399 brackets define a region of reduced intensity where prior observation at higher  
1400 magnification resulted in the loss of an unknown sub-nm material that is readily  
1401 vaporized under the electron beam. The vertical arrows indicate holes in the  
1402 film, rimmed with concentrated material. The diagonal arrow indicates a particle  
1403 ring, which appears to result from the concentration of particles around the  
1404 perimeter of an evaporated liquid droplet.

1405

1406 **Figure 11.** High-angle annular dark-field (HAADF) image of a particle ring. The  
1407 ring has a diffuse boundary of concentrated sub-nm material and is studded with  
1408 dense aggregates of 0.5 to 2 nm radius particles.

1409

1410 **Figure 12. a)** The top section of the ECOMA payload for mesospheric particle  
1411 studies with booms deployed. The ECOMA particle detector from IAP is in the  
1412 centre and the MAGIC particle sampler from MISU/NRL in the foreground. Other  
1413 instruments are temperature probes from IAP (left, right) and ionospheric  
1414 instrumentation from the Technical University Graz, Austria (booms). **b)** Top  
1415 section with the two MAGIC samplers visible and one half of the nosecone  
1416 attached. For the 2008 campaign one MAGIC sampler was replaced by a mass  
1417 dummy, and the two IAP temperature probes were replaced by the particle  
1418 detectors from University of Tromsø, Norway and Dartmouth College, USA. **c)**  
1419 Photo showing the extension added in the ECOMA 2007 and 2008 campaigns to  
1420 protect the MAGIC pin exit hole and the volume around it from the possible  
1421 airflow through the ECOMA detector and from the high temperatures during re-  
1422 entry.

1423

1424 **Figure 13.** The different kinds of hydrocarbon contamination seen on the TEM  
1425 grids in MAGIC sampler #1 on ECOMA-01. Low resolution TEM image showing **a)**  
1426 lighter, irregularly shaped hydrocarbon blobs with central dark spot on grid 1,  
1427 and **b)** darker, opaque, roundish hydrocarbon blobs on grid 7. **c)** Higher  
1428 resolution HAADF image showing “snow flake” type hydrocarbon contamination  
1429 on grid 2 with large amounts of nanometre sized particles with composition  
1430 typical to stainless steel.

1431

1432 **Figure 14.** High-angle annular dark-field (HAADF) images of areas on ECOMA-01  
1433 grids 1, 2, 3 and 7 exposed to the atmosphere at 68.4-73.2 km, 78.1-86.2 km,  
1434 88.9-92.7 km, and 111.0-115.8 km altitude, respectively. Grids 2 and 3 show at  
1435 least one order of magnitude more sub-10 nm particles per unit area than grids 1  
1436 and 7. EDX spectra show that the particles have a composition similar to  
1437 stainless steel.

1438

1439 **Figure 15. (a)** Sketch of the TEM grid with aperture showing the 4 sampling  
1440 squares in the centre and the on-grid reference square under the Cu mask, that  
1441 was analysed both before and after flight. (b) Sketch of the sampling head on the  
1442 collection pin with Cu mask, or grid aperture (grid apertures were not used for  
1443 the two flights in 2005). (c) Photo of the copper grid cap, Cu mask (grid  
1444 aperture), TEM grid, and the fully assembled sampling pin.

1445

1446 **Figure 16. a)** TEM image of an agglomerated particle found on the grid exposed  
1447 to the NLC during the flight of ECOMA-04 from Andøya Rocket Range in June  
1448 2008. Panels **b) to n)** are energy-filtered images showing the signal from **b) S, c)**  
1449 **O, d) Na, e) Cu, f) Si, g) Mn, h) Mg, i) F, j) Cr, k) K, l) Fe, m) Cl, and n) Ca.**

1450

1451 **Figure 17.** TEM images of agglomerated particles found **a)** on the on-grid  
1452 reference square under the mask on the grid exposed to the NLC, and **b)** and **c)**  
1453 on the reference grid that was not exposed to the atmosphere.

1454

1455 **Figure 18.** The top deck configuration of the PHOCUS sounding rocket payload  
1456 launched from Esrange Space Center in July 2011 with the MAGIC particle  
1457 sampler circled. Other instruments are the positive ion probe, electron probe,  
1458 and the Faraday rotation experiment (the four booms, Technical University  
1459 Graz); the IR airglow photometers and NLC photometers (the four black  
1460 cylinders, MISU); the two detectors for charged particles (University of Tromsø  
1461 (right) and IAP (left)); and the forward-looking water vapour radiometer in the  
1462 centre (Chalmers University of Technology).

1463

1464 **Figure 19.** The two types of sampling pins prepared for the PHOCUS sounding  
1465 rocket. Panel **a)** shows the normal open type used for four of the reference grids  
1466 and the exposed grid, and **b)** shows the covered type used for three reference  
1467 grids where the TEM grid is completely covered by a Cu cap.

1468

1469

1470

1471 **Table 1.** ECOMA-04 composition analysis before and after flight. Numbers given  
 1472 are the atomic %. The colour code is as follows: white marks signals below the  
 1473 detection limit both before and after flight; green marks elements that did not  
 1474 change; blue marks elements that were reduced after flight; and red marks  
 1475 elements that were increased after flight. The red squares mark the elements  
 1476 where there was a significant change.

1481 **Table 2.** The amount of particles found on the ECOMA-06 MAGIC grids. The  
 1482 mesospheric particle density is calculated assuming a sticking efficiency of 100  
 1483 %. The numbers in parenthesis after the mean radius are the minimum and  
 1484 maximum radii (or spread) of the measured particle size distribution.

Grid	Particles on grid ( $\mu\text{m}^{-2}$ )	Mean radius (nm)	Sampled altitude (km)	Particle density ( $\text{cm}^{-3}$ )
1	76.3	4.51 (2.5 - 9)	65.5 - 70 (4.5 km)	$1.7 \times 10^4$
2	13.0	4.51 (2.5 - 9.8)	75 - 87 (12 km)	$1.1 \times 10^3$
3	23.2	4.93 (3.3 - 9.8)	90 - 94 (4 km)	$5.8 \times 10^3$
4	14.5	4.13 (2.5 - 9.8)	96.5 - 100.5 (4 km)	$3.6 \times 10^3$
5	11.0	4.55 (2.5 - 12.7)	Reference	-
6	31.4	4.13 (2-12.7)	Reference	-

<b>HCC<sup>1</sup></b>	79-85 km			-	80-90 km		77-95 km	81-95 km	70-95 km	81-82 km
<b>NLC</b>	No, outside NLC season			No, outside NLC season and region	No, outside NLC season		Yes 82-83 km	Yes <sup>2</sup> 82-85 km	Yes 81-85 km	Yes 81-82 km
	Non-NLC conditions, too warm for ice particles to form						Confirmed presence of ice by the on board NLC photometers			
<b>Grid type</b>	30 nm continuous carbon film on 200 lines/inch copper mesh			Ultra-thin C on holey C & 400 lines/in. Cu mesh	30 nm continuous C on 200 lines/in. Cu mesh, plasma cleaned (etched)		30 nm continuous C film on 200 lines/in. Cu mesh, plasma cleaned (etched)			Ultra-thin C on holey C & 400 lines/in. Cu mesh
<b>Com- ments</b>	Hydrocarbon film and particle contamination. Low contrast due to thick C film.			Particle cont. (too many particles)	Thick hydrocarbon film and drops, and lots of stainless steel particle contamination		Agglom. particles, no new nm particles	Particle contamination, C film heavily damaged, probably during transport		No cont., no in-flight sampled particles of any size

1489

1490 <sup>1</sup> HCC = heavy charge carriers. Indicates if charged particles were detected by  
1491 other instruments and in what altitude region.

1492 <sup>2</sup> Presence of NLC but confirmed absence of PMSE.
