5

6

7 **Fast-flowing ice streams carry ice from the interior of the Antarctic Ice Sheet**
8 **toward the coast. Understanding how ice-stream tributaries operate and how**
9 **networks of them evolve is essential for developing reliable models of the ice**
10 **sheet's response to climate change¹⁻⁶. A particular challenge is to unravel the**
11 **spatial complexity of flow within and across tributary networks. Here I define a**
12 **measure of planimetric flow convergence, which can be calculated from satellite**
13 **measurements of the ice sheet's surface velocity, to explore this complexity. The**
14 **convergence map of Antarctica clarifies how tributaries draw ice from its interior.**
15 **The map also reveals curvilinear zones of convergence along lateral shear margins**
16 **of streaming, and abundant ripples associated with nonlinear ice rheology and**
17 **changes in bed topography and friction. Convergence on ice-stream tributaries**
18 **and their feeding zones is uneven and interspersed with divergence. For individual**
19 **drainage basins as well as the ice sheet as a whole, fast flow cannot converge or**
20 **diverge as much as slow flow. I therefore deduce that flow in the ice-stream**
21 **networks is subject to mechanical regulation that limits flow-orthonormal strain**
22 **rates. These findings provide targets for ice-sheet simulations and motivate more**
23 **research into the origin and dynamics of tributarization.**

24

25 Ice streams have been studied by geomorphological analysis of their surface and
26 bed forms⁷⁻⁹, radar and seismic imaging of their internal and basal properties⁹⁻¹³,
27 borehole measurements¹⁴, and thermomechanical modelling¹⁵⁻²¹. Models can mimic ice-
28 stream flow in numerical simulations¹⁶⁻²⁰ but are still probing the uncertain physics of
29 basal-lubricated ice motion coupled with subglacial hydrology¹⁶⁻¹⁸ and of shear-margin
30 development and migration²¹. That subglacial geology can influence the location of ice
31 streams, and major bed-topographic channels focus their flow, and in turn be shaped by
32 it, is recognized^{11,22}. But how networks of interacting ice-stream tributaries form, and
33 what controls their dendritic (sometimes anastomosing) pattern, remain enigmas.
34 Morphometric analysis of their flow field can shed light on these questions by
35 uncovering order behind its complexity.

36 The essence of any non-uniform flow pattern is its directional variability.
37 Tributarization of ice-sheet flow inherently involves flow merging and splitting, as
38 evident from how flowlines converge/diverge, which is quantifiable as spatial rates of
39 change of flow direction. To investigate this amorphous geometry, I propose a novel
40 measure of planimetric flow convergence C , based on the surface ice-flow direction
41 $\theta(X, Y)$ (measured clockwise from the Y -axis in radian; X and Y are horizontal
42 coordinates), and compute a near-continuous visualization of C across Antarctica. Away
43 from singular points at saddles and summits²³, θ is continuous and differentiable. I
44 define convergence as its rate of change across flow $C = \partial\theta/\partial n$, with n pointing left-
45 perpendicular to flow; thus $C > 0$, < 0 and $= 0$, respectively, if the flow is locally
46 converging, diverging and parallel, whether or not it curves (Methods; Supplementary
47 Fig. 1). Notice ‘divergence’ herein means $C < 0$, not divergence of a vector field; and
48 $\partial\theta/\partial s$, where s points along flow, quantifies flow curvature, not merging/splitting.
49 Locally, C equals the cross-flow compressive strain rate divided by flow speed U

50 (Methods) so it can sensitively detect convergence/divergence in slow flow. The C -
51 values reported below for ice streams fall within \pm several km^{-1} , about four orders of
52 magnitude less than C for a kitchen drain vortex.

53 I derived the θ -field from the Interferometric Synthetic Aperture Radar-
54 (INSAR-) based surface velocity map of Antarctica⁶. Then I computed C by a kriging
55 procedure, which treats θ as an intrinsic random field with auto-correlation properties
56 obeying its variogram (Supplementary Fig. 2) and evaluates C as a linearly-unbiased
57 estimate of the directional derivative of θ , while suppressing effects of uncorrelated
58 noise in θ (Methods).

59 The convergence map (Fig. 1) bears an unmistakable imprint of ice-stream
60 networks and shows two distinct convergence textures (Figs 1b–f and 2) that broadly
61 occupy regions of different speeds. ‘Chaos’ texture, characterized by an intricate pattern
62 of intense convergence and divergence alternating over distances of several kilometres
63 or less, dominates the interior, mountains, ice rises and ridges, where $U \lesssim 20 \text{ m a}^{-1}$. Its
64 convergence pattern is unreliable and neglected from analysis, because it inherits
65 abundant artefacts from the INSAR velocity and shows weak noise suppression
66 expected from the low flow speeds, which are comparable to errors in the INSAR
67 velocity measurements (a few to 17 m a^{-1} ; ref. 6). ‘Streaming’ texture undulates gently
68 over longer distances and occurs on ice-stream tributaries/trunks, outlet glaciers and ice
69 shelves, where $U \gtrsim 20 \text{ m a}^{-1}$. I call the respective regions ‘chaos regions’ and
70 ‘streaming regions’. Besides these textures, long curvilinear convergent or divergent
71 zones several kilometres wide commonly inhabit tributary/trunk shear margins and ice-
72 rise/ridge boundaries, reflecting strong lateral compression or extension where flank
73 flow joins streaming flow. Some convergent zones merge and extend downstream at
74 tributary confluences.

75 The map evidences rich structures in the switch from deformation-dominated
76 slow flow to basal-slip dominated streaming flow, extending earlier inferences (from the
77 velocity field)⁶ that non-uniformities pervade ice-sheet flow. Notably, in slower-moving
78 areas of streaming regions, where ice flow feeding and within ice-stream tributaries is
79 expected to merge overall as it accelerates¹³, convergence is markedly heterogeneous
80 (e.g. where $20 \lesssim U \lesssim 200 \text{ m a}^{-1}$ in Figs 1b–f). Here, sinuous ripples in C of both signs
81 are widespread, often with spacings of $O(10)$ km and axes diagonal or sub-parallel to
82 flow; some ripples grade into the fine-scale chaos. The faster flow on ice-stream and
83 outlet-glacier trunks is smoother in texture, but not devoid of ripples.

84 Comparison of the convergence map with the ice sheet’s basal topography from
85 the BEDMAP2 dataset²⁴ confirms that some ripples—notably neighbouring pairs signed
86 oppositely in C —record surface velocity perturbations associated with flow over
87 subglacial peaks or ridges/steps²⁵ (Fig. 2; ellipses in Figs 1d,f). Ripples occurring far
88 from shear margins where the bed appears smooth are likely caused by ice-rheological
89 softening²⁶ (thus they may indicate failed or developing shear margins) or flow over
90 sticky/slippery spots^{25,27}. The latter possibility is supported by ice-flow modelling for
91 Pine Island Glacier and Thwaites Glacier²⁸, which infers ribbed domains of high basal
92 friction with similar spacing and orientation as ripples (Supplementary Fig. 3).
93 Comparing the convergence in chaos regions with their bed roughness is not
94 undertaken, because it is error-prone and much of the interior is poorly resolved by
95 BEDMAP2²⁴.

96 Fundamental properties of Antarctic ice flow are revealed by the tower-shaped
97 plot of speed U against convergence C (Fig. 3a). At each speed, C ranges positive and
98 negative far from the theoretical small divergence for a radially-spreading ice sheet ($C \approx$
99 $-1/(60U) \text{ km}^{-1}$ for 3-km thick ice receiving 0.1 m a^{-1} accumulation; Methods). This

100 bifurcation of C is a hallmark of flow within tributary networks, which converges in
101 some areas and diverges in others. Except at speeds $\geq 2,000 \text{ m a}^{-1}$, where localized flow
102 near ice-shelf edges and cracks causes a minor enhancement in convergence/divergence,
103 the tower flanks indicate monotonic decay of the extreme values of C with U , and a
104 maximum speed for flow converging/diverging at each rate. Blank regions outside the
105 tower reflect the absence of strongly converging/diverging fast flow.

106 Furthermore, the C -values at each speed are concentrated in a histogram peak
107 much narrower than their range (well within $\pm 0.2 \text{ km}^{-1}$; thus the colours in Figs 1 and
108 2b portray most C -values of streaming texture and saturate mainly extreme values of
109 chaos texture), and the convergence and divergence at half-peak height, C_+ and C_- ,
110 decay with U for $U \lesssim 2,000 \text{ m a}^{-1}$ (Figs 3c,d). These decays and the tower flanks in Fig.
111 3a imply that slow flow can converge and diverge more than fast flow across the
112 grounded portion of the ice sheet. This macroscopic speed dependence of the C -value
113 distribution holds regardless of the convergence in chaos regions and accords with: (1)
114 observed relationships between convergence and velocity patterns (e.g. Fig. 2) and (2)
115 the expectation that basal obstacles and sticky/slippery spots disturb fast flow less
116 (bifurcate C less) than slow flow. However, since this ‘tower dependence’ holds across
117 different parts of the system (ice-stream trunks, tributaries, feeding zones, margins) and
118 two orders of magnitude in U , it must have a more general mechanical origin than
119 envisioned in (2)—as discussed shortly. The dependence is robust and universal. It is
120 corroborated by increasing smoothness of the θ -field with speed (Supplementary Fig. 2)
121 and insensitive to rekriging with the flow-direction variogram of streaming regions
122 (Supplementary Figs 4b–d). Tower-shaped plots are also found for individual drainage
123 basins hosting different ice-stream networks (Fig. 3e). Although a spurious tower
124 dependence could arise from corruption of C in slower-flowing streaming regions by

125 INSAR-velocity errors, error analysis excludes this possibility (Methods;
126 Supplementary Fig. 5). As is consistent with overall capture of ice into tributaries, the
127 C -value distribution is asymmetric for $20 \lesssim U \lesssim 200 \text{ m a}^{-1}$ (Figs 3a,c,d); in this range,
128 which encompasses streaming onset and tributary feeding zones, the area of converging
129 flow exceeds that of diverging flow by 12.2%; the mean convergence is $+0.012 \text{ km}^{-1}$.

130 The tower dependence teaches us about the dynamics as well as latent geometry
131 of tributarized flow. Since C is flow-orthonormal compressive strain rate over U , the
132 ubiquitous tower shape may be due primarily to this $1/U$ -normalization (which enables
133 conversion between geometry and deformation), modulated by flow-orthonormal strain
134 rates. This interpretation is valid because the strain-rate distribution is weakly speed-
135 dependent for $U \lesssim 2,000 \text{ m a}^{-1}$ (Fig. 3b): at such speeds, the decay curves in Fig. 3c
136 follow $U \propto |C_{\pm}|^{-1.4}$ approximately, so strain rates have the half-peak range $U |C_{\pm}| \propto$
137 $U^{0.29}$. (The diffused tower flanks are harder to trace for curve fitting.) While these power
138 laws indicate deviation of the tower dependence from $U \propto |C_{\pm}|^{-1}$ expected from the
139 normalization, the critical discovery here is that the dependence occurs because flow-
140 orthonormal strain rates at vastly different speeds have similar distributional widths,
141 with half-peak range $\sim 10^{-2} \text{ a}^{-1}$ (Fig. 3b). This behaviour points to concerted mechanical
142 regulation of the tributarized flow.

143 Deciphering the mechanisms behind the regulation is important for
144 understanding the ice-stream networks because it underlies an entire hierarchy of
145 tributarization structures. Indeed, any successful theory of the networks must explain
146 the observed speed dependence of the distribution of C , or equivalently, of strain rate
147 (as summarized by the power laws), which is a signature of their dynamical complexity.
148 The mechanisms presumably involve ice rheology because non-zero C implies

149 deformation; strain rates may be limited by internal feedbacks on ice viscosity, e.g. via
150 its temperature and strain-rate controls or anisotropy, as occur at shear margins^{15,21}. But
151 local rheological descriptions (based on Glen's law) seem unable to predict the
152 dependence directly, because they relate stress to strain rates (velocity gradients), not
153 speed. The mechanisms must also involve the spatial connectedness of flow in the
154 networks, because regulation acts on the surface strain-rate tensor resolved in a flow-
155 related direction. Glaciological theories have yet to address such non-local aspect of ice
156 streaming. The concept of flow routing in directions governed by surface slope in a
157 mass-conserving manner, as used to compute 'balance velocities'^{29,1} for the ice sheet
158 (velocities that keep its surface at steady state, given an accumulation-rate pattern),
159 offers a tantalizing clue to the mechanisms, because the plot of balance speeds against
160 convergence found from such routing forms a diffused tower, even though its details are
161 incorrect (Supplementary Fig. 6). Pinpointing the mechanisms will require deeper
162 theoretical analysis of three-dimensional ice flow with the convergence data. State-of-
163 the-art simulations¹⁶⁻¹⁹ can aid this enquiry, but it is important to scrutinize how valid
164 are their parameterizations of basal processes for predicting migrating and branching ice
165 streams.

166 Future research should go beyond tuned numerical simulations to strive for
167 holistic understanding of ice-stream systems, by exploiting tools for studying spatial
168 networks (e.g. ref. 30) and measures beside convergence. Immediate extensions include
169 mapping flow convergence for the Greenland Ice Sheet and smaller ice masses,
170 resolving chaos regions with accurate velocity measurements, and tracking how
171 convergence varies with time.

288 C . **b**, U versus UC (points, lower scale) and versus half-peak strain rates UC_+ and UC_-
289 (curves, upper scale). See **d** for definitions of C_+ and C_- . **c**, Half-peak convergence C_+
290 and C_- of histograms of C at different speeds; C_- reflected into $C > 0$ (dashed curve)
291 highlights excess C_+ at intermediate speeds. **d**, Unit-area histogram of C at $U = 100 \text{ m}$
292 a^{-1} . As at other speeds, the distribution is non-Gaussian and resembles the Laplace
293 distribution. **e**, U versus C for individual drainage basins in Fig. 1a.

294 **Methods**

295 **Definition of convergence C .**

296 Ice-flow convergence (or divergence) is mentioned but rarely quantified in glaciology.
297 My definition $C = \partial\theta/\partial n = \mathbf{n}\cdot\nabla\theta$ is purely geometrical (Supplementary Fig. 1a) and
298 involves no forces nor conservation laws. Equivalently, C measures the local curvature
299 of curves orthonormal to flow lines, with its sign positive when the curves are concave
300 towards flow (Supplementary Fig. 1c). The curvature of flow lines is independent of C
301 and does not quantify flow merging/splitting (as said in the text), but may be studied in
302 future work for additional geometric properties of tributarized ice flow.

303 By considering how fast an ice element shortens laterally as it moves down flow
304 at speed U , C can be linked to the cross-flow compressive strain rate (Supplementary
305 Fig. 1b). Define a local coordinate system (x, y) centred at point P and the local velocity
306 field as (u, v) , with x and u oriented along flow, and y and v across, such that $(u, v) = (U,$
307 $0)$ at P, then $C = -(\partial v/\partial y)/U$ there.

308 For a hypothetical circular ice sheet of constant thickness h spreading radially at
309 steady state, receiving constant accumulation rate a and losing mass by calving only,
310 geometry gives $C = -1/r$ and mass conservation gives $U = ar/2h$ at radius r . Eliminating
311 r yields $C = -a/2hU$, as used in the text.

312 An estimate of C in a vortex above a drain hole of diameter D is, assuming
313 cylindrical symmetry for the flow, $2/D$ ($= 5\times 10^4 \text{ km}^{-1}$ if $D = 4 \text{ cm}$).

314

315 **Estimating C from surface velocity.**

316 INSAR measurements of Antarctic ice-surface velocity \mathbf{v} on a 450-m polar
317 stereographic projection (X - Y) grid^{6,31} with secant plane at 71°S were converted to θ

318 measuring clockwise from the Y -axis on the same grid. All of my results pertain to the
319 collection period of these measurements: 1996 to 2011. The projection is conformal.
320 The θ -field inherits noise (measurement errors, artefacts), irregular boundaries (e.g. ice-
321 sheet margin) and data voids from \mathbf{v} . Convergence C is a gradient estimate of this field.
322 To estimate C , I used kriging interpolation^{32,33} because this geostatistical approach can
323 handle irregular-spaced input data, and, when yielding estimates, it accounts for spatial
324 autocorrelation of the input data (shown by their variogram) and filters and smoothes
325 them accordingly to extract signals. My method is elaborated below. In contrast, simple
326 finite differencing of the θ -values would yield estimates of C more strongly dominated
327 by noise, and the choice of any subsequent spatial filtering to smooth C would be
328 difficult to justify. One could also find C via the lateral strain rate above, but then
329 kriging is needed several times for estimating (from \mathbf{v}) both strain-rate components and
330 flow direction; the latter is needed for resolving the strain-rate components across flow.

331 As in most kriging practices, first the experimental variogram $\gamma(h)$ for all θ -
332 values, where h is separation distance, was compiled (Supplementary Fig. 2; filled
333 circles). In calculating semivariance γ , mismatch between flow directions is quantified
334 by the squared norm of the difference between their unit vectors to avoid problems with
335 circular statistics^{34,35}. $\gamma(h)$ shows that flow directions on the ice sheet are well correlated
336 at $h \lesssim 4$ km (Supplementary Fig. 2; filled circles); this suggested the kriging range used
337 below.

338 Next, assuming a fitted variogram model (solid curve, Supplementary Fig. 2)
339 and 6 km as the range, Continuous-Part Kriging (CPK)³³ was applied at each grid point
340 to re-estimate θ from the input data of θ there and in the neighbourhood. For areas
341 without voids, the interpolation uses > 500 neighbouring grid points. The non-zero
342 nugget $\gamma(0)$ represents uncorrelated noise in θ due to measurement errors and sub-grid-

343 scale effects. Its use in CPK suppresses noise so that the re-estimated flow direction,
344 $\theta_K(X, Y)$, is a smoothed version of the θ -field and approximates its continuous (signal)
345 part³³. The fitted variogram model function is designed to be parabolic at $h = 0$ to make
346 θ_K continuous and differentiable^{33,35}.

347 The final step computed C at each grid point as the gradient of θ_K in the
348 direction left-perpendicular to θ_K , by using a method where spatial differentiation is
349 embedded in CPK³⁶. The kriging system—the interpolation sum and equations for the
350 kriging weights and for the kriging standard derivation—is detailed in ref. 36. The same
351 variogram model and range as before were used. In both CPK steps, flow directions
352 were treated vectorially, with the interpolation sum evaluated as the Fisher sum^{35,37} of
353 direction cosines. The kriging standard deviation (a statistical error estimate for the
354 Fisher sum) was converted to σ_C , the kriging standard deviation for C , by normalizing
355 its size by the sum magnitude. Throughout variogram compilation and kriging, true
356 geodetic distances found by correcting grid distances with the projection scale factor
357 were used.

358 The grid spacing imposes a theoretical maximum limit on the gradient of θ that
359 two neighbouring grid points can resolve, of $\approx \pi/(450 \text{ m})$ or 6.98 km^{-1} . Yet CPK can
360 produce unrealistic values of $|C|$ exceeding this limit because it uses many grid points
361 in optimal estimation. Hence values in the output convergence grid were clipped to
362 within $\pm 6.98 \text{ km}^{-1}$. Clipping occurred in chaos regions only.

363 The flow-speed and convergence data in Supplementary Fig. 6 derive from the
364 Antarctic balance-velocity model of ref. 1 (updated velocities based on newer ice-sheet
365 surface topography³⁸ after recalculation by J.L. Bamber). Convergence was estimated
366 from flow direction by a kriging procedure like the one above.

367

368 **Error analysis and robustness of the tower dependence.**

369 $\theta_K(X, Y)$ was validated by checking that the residuals $\theta_K - \theta$ are unbiased and
370 uncorrelated, and σ_θ^2 (kriging variance for θ_K) adequately accounts for their variance in
371 streaming regions. Typically, $\sigma_\theta \approx 5^\circ$ in these regions.

372 In contrast, kriged estimates of C cannot be validated because independent
373 estimates of C based on direct strain-rate measurements rather than based on only
374 velocity measurements are unavailable. Although the kriging standard deviation σ_C at
375 each grid point is known, it does not reflect the local variability of the C -field, so it
376 cannot be used to assess how errors in C impact the results in Figure 3 (see further
377 discussion below). Specifically, the kriging standard deviation is a global measure of
378 uncertainty that accounts only for the variogram and the configuration of kriging
379 interpolation grid points (e.g. refs. 32, 33). σ_C is near-uniform ($\approx 0.13 \text{ km}^{-1}$) in
380 streaming regions; expectedly, it rises within a few grid spacings of boundaries and data
381 voids and fluctuates strongly in chaos regions, attesting the unreliability of the kriged
382 estimates of C in these areas.

383 As the text describes, in chaos regions, low flow speeds allow measurement
384 errors in \mathbf{v} to corrupt θ and obscure these regions' true convergence. To demonstrate
385 this effect, I conducted the experiment in Supplementary Fig. 7 where, in an otherwise
386 parallel flow, deliberate error in θ was introduced to a grid point, causing a convergence
387 dipole. More errors in the neighbourhood can then produce the random-looking, short-
388 scale convergence-divergence pattern in chaos regions. Comparing θ_K to θ in chaos
389 regions confirms that θ_K has been smoothed to some extent by kriging, but kriging
390 cannot negate such errors to recover convergence reliably. Not surprisingly, weak traces
391 of chaos are visible in some slow parts of streaming regions (Fig. 1); their short length-
392 scale precludes their being mistaken as convergence ripples.

393 Whether errors in U and C can upset my inference from Figure 3 of the tower-
394 shaped speed dependence of the C -distribution needs consideration. Errors in U ($\lesssim 17$
395 m a^{-1})⁶ are negligible in the large speed range of interest. To derive error estimates for
396 C , I use the knowledge that C -values in streaming regions portray spatially-coherent
397 features on the convergence map. Whether such feature is a convergence ripple, a
398 curvilinear shear-margin zone, or an area of near-parallel or uniformly
399 converging/diverging flow on an ice stream, a key characteristic of it is that C does not
400 vary much across the feature. This idea motivates the calculation of the mean \bar{C} and
401 standard deviation σ of the C -values in separate ‘block regions’ across the ice sheet; σ is
402 then an error estimate of C for each block. The tower dependence is assured if some
403 blocks with low U have convergence statistics ($|\bar{C}| \pm \sigma$) more extreme than the most
404 extreme block convergence/divergence estimates found at higher U . The results, in
405 Supplementary Figure 5, confirm these instances and the integrity of the dependence.
406 The block size in this analysis, 25 by 25 grid points, is chosen to be not too large
407 compared to the typical size of the features.

408

409 **Removal of spurious data, and sensitivity to choice of variogram model.**

410 The raw plot of U versus C from my kriging calculation showed outliers from the tower
411 (red points, Supplementary Fig. 4a). Examination of these outliers with the input
412 velocity field \mathbf{v} showed them to be false ‘excursions’ caused by: (i) isolated grid
413 points—often on the edge of data voids—where \mathbf{v} (thus also U) is anomalous compared
414 to that in adjacent areas, or (ii) positions one or two grid spacings from ice-free areas
415 (e.g. mountains) or data voids where kriging uncertainty (σ_C) becomes high and C is
416 anomalous compared to C in adjacent areas. Fig. 3a is the processed plot after results

417 from these places and from all grid points within two grid spacings of boundaries and
418 voids have been excluded. The same processing preceded the making of Figs 3b–e.

419 Finally, my kriging procedure can be criticized for assuming a best-fit variogram
420 model for the whole ice sheet (including chaos regions), when ultimately, the C -values
421 in chaos regions are deemed unusable and excluded from analysis. To show that the
422 paper’s conclusions are not hinged on this assumption, I repeated the kriging to compute
423 C in streaming regions, this time assuming the best-fit variogram model for regions
424 where $U > 20 \text{ m a}^{-1}$ (dashed curve, Supplementary Fig. 2). The resulting convergence
425 map looks practically the same as Figure 1 except it is less smoothed and conveys more
426 spatial details/noise, notably in slower areas of streaming regions. This is expected
427 because the new model γ , which is an average estimate for the speed range $U > 20 \text{ m a}^{-1}$
428 ¹, underestimates γ for ice flow at the lower end of this range. Crucially, while rekriging
429 changed all convergence estimates numerically, all essential mapped features (e.g.
430 ripples) discussed in the text remain valid, and remaking of Figs 3a,c,d shows negligible
431 change in both the C -distribution and its speed dependence (Supplementary Figs 4b–d).

432

433 **Data availability.** Gridded data of the Antarctic Ice Sheet’s flow convergence and
434 cross-flow strain rate are archived at <http://doi.pangaea.de/10.1594/PANGAEA.841137>.

435

436 **Code availability.** The code used to compute the variogram of flow direction and the
437 convergence values is available on request from Felix Ng (f.ng@sheffield.ac.uk).

13 **Supplementary Figure 2. Vectorial variogram for ice-flow directions on the**

14 **Antarctic Ice Sheet.** Following ref. 34, empirical variogram data (symbols) for flow in

15 different speed ranges were calculated by $\gamma(h) = \Sigma |z(X,Y) - z(X+dX, Y+dY)|^2 / (2N(h))$,

16 where γ is semivariance, z is unit vector representing flow direction θ , h is geodetic

17 distance between each pair of positions (X, Y) and $(X+dX, Y+dY)$, and summation is

18 done over all non-repeating position pairs (N being their total number) falling in

19 different bins of h . Semivariance decreases with speed at all distances. Steep slope of

20 $\gamma(h)$ near the origin at low speeds indicates spatial non-smoothness of θ in chaos

21 regions; its low slope at high speeds indicates smoothness of θ in streaming regions.

22 Solid curve is the fitted variogram model for the whole ice sheet: $\gamma = A_0 + A_1(1 -$

23 $\exp(-((h^2+A_5^2)^{0.5}-A_5)/A_2)) + A_3(1 - \exp(-((h^2+A_5^2)^{0.5}-A_5)/A_4))$, with parameters $A_0 =$

24 0.07 (nugget), $A_1 = 0.133$, $A_2 = 0.85$, $A_3 = 0.24$, $A_4 = 28$, $A_5 = 2$. Dashed curve is the

25 fitted variogram model for regions where $U > 20 \text{ m a}^{-1}$ (thus, streaming regions mostly):

26 $\gamma = A_0 + A_1(1 - \exp(-((h^2+A_3^2)^{0.5}-A_3)/A_2))$, with $A_0 = 0.002$ (nugget), $A_1 = 0.188$, $A_2 =$

27 33, $A_3 = 0.3$.

51

52 **Supplementary Figure 5. Binned analysis of convergence and its errors for**

53 **contiguous block regions across the ice sheet.** A block, measuring 25 grid points on a

54 side, is sampled if it has $\leq 10\%$ void pixels and its speed range falls entirely within a

55 speed bin. \bar{C} denotes the mean of C -values in the block, and σ their standard deviation.

56 In the figure, each bin gathers blocks with similar speeds U ; grey bar indicates the range

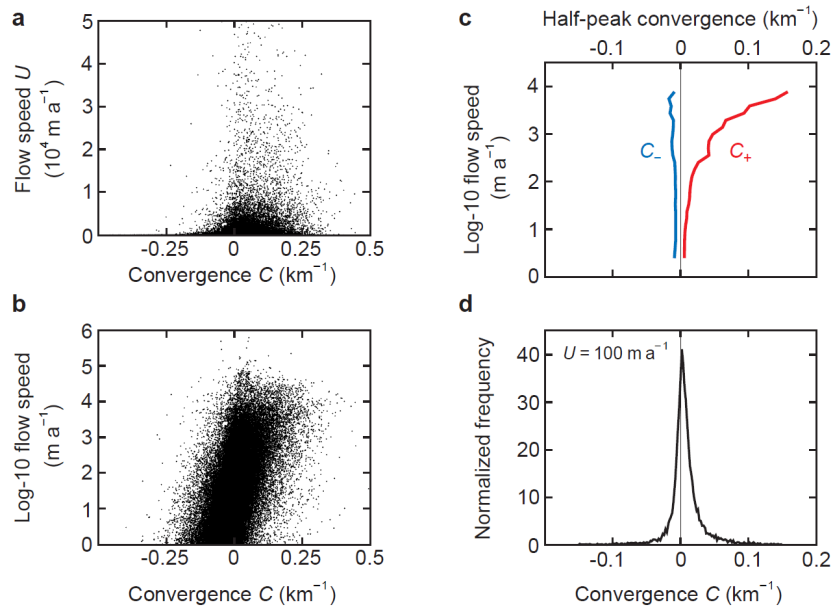

57 of \bar{C} ; white box indicates the expanded range from minimum $\bar{C} - \sigma$ to maximum $\bar{C} + \sigma$.

58 Two sets of ‘dot and whiskers’ plot \bar{C} and $\bar{C} \pm \sigma$ of the sample whose $\bar{C} + \sigma$ is the least

59 (blue), and of the sample whose $\bar{C} - \sigma$ is the greatest (red). That such samples in some

60 lower-speed bins lie outside the expanded range of some higher-speed bins confirms

61 that kriging uncertainty in C cannot nullify its ‘tower dependence’ on U .
