**Abstract.** Combustion of fuels in the residential sector for cooking and heating results in the emission of aerosol and aerosol precursors impacting air quality, human health, and climate. Residential emissions are dominated by the combustion of solid fuels. We use a global aerosol microphysics model to simulate the impact of residential fuel combustion on atmospheric aerosol for the year 2000. The model underestimates black carbon (BC) and organic carbon (OC) mass concentrations observed over Asia, Eastern Europe, and Africa, with better prediction when carbonaceous emissions from the residential sector are doubled. Observed seasonal variability of BC and OC concentrations are better simulated when residential emissions include a seasonal cycle. The largest contributions of residential emissions to annual surface mean particulate matter (PM<sub>2.5</sub>) concentrations are simulated for East Asia, South Asia, and Eastern Europe. We use a concentration response function to estimate the human health impact due to long-term exposure to ambient PM<sub>2.5</sub> from residential emissions. We estimate global annual excess adult (> 30 years of age) premature mortality (due to both cardiopulmonary disease and lung cancer) to be 308 000 (113 300–497 000, 5th to 95th percentile uncertainty

range) for monthly varying residential emissions and 517 000 (192 000–827 000) when residential carbonaceous emissions are doubled. Mortality due to residential emissions is greatest in Asia, with China and India accounting for 50% of simulated global excess mortality. Using an offline radiative transfer model we estimate that residential emissions exert a global annual mean direct radiative effect between  $-66$  and  $+21$  mW m<sup>-2</sup>, with sensitivity to the residential emission flux and the assumed ratio of BC, OC, and SO<sub>2</sub> emissions. Residential emissions exert a global annual mean first aerosol indirect effect of between  $-52$  and  $-16$  mW m<sup>-2</sup>, which is sensitive to the assumed size distribution of carbonaceous emissions. Overall, our results demonstrate that reducing residential combustion emissions would have substantial benefits for human health through reductions in ambient PM<sub>2.5</sub> concentrations.

## 1 Introduction

Combustion of fuels within the household for cooking and heating, known as residential fuel combustion, is an important source of aerosol emissions with impacts on air quality and climate (Ramanathan and Carmichael, 2008; Lim et al., 2012). In most regions, residential emissions are dominated by the combustion of residential solid fuels (RSFs, see Table A1 for list of acronyms used in the study) such as wood, charcoal, agricultural residue, animal waste, and coal. Nearly 3 billion people, mostly in the developing world, depend on the combustion of RSFs as their primary energy source (Bonjour et al., 2013). RSFs are usually burnt in simple stoves or open fires with low combustion efficiencies, resulting in substantial emissions of aerosol. It has been suggested that reducing RSF emissions would be a fast way to mitigate climate and improve air quality (UNEP, 2011), but the climate impacts of RSF emissions are uncertain (Bond et al., 2013). Whilst it is clear that RSF combustion has substantial adverse impacts on human health through poor indoor air quality, there have been few studies quantifying the impacts on outdoor air quality and human health. Here, we use a global aerosol microphysics model to estimate the impacts of residential fuel combustion on atmospheric aerosol, climate, and human health.

Residential emissions due to the small-scale combustion of biomass and fossil fuels used for cooking, heating, lighting, and auxiliary engines include black carbon (BC), particulate organic matter (POM), primary inorganic sulfate, and gas-phase SO<sub>2</sub>. Residential emissions contribute substantially to the global aerosol burden, accounting for 25 % of global energy-related BC emissions (Bond et al., 2013). In China and India, residential emissions are even more important, accounting for 50–60 % of BC and 60–80 % of organic carbon (OC) emissions (Cao et al., 2006; Klimont et al., 2009; Lei et al., 2011). The combustion of residential fuels also emit volatile and semi-volatile organic compounds that lead to the production of secondary organic aerosols via atmospheric oxidation. Residential emissions are dominated by emissions from RSFs in many regions, due to poor combustion efficiency of RSFs and extensive use across the developing world (Bond et al., 2013). In China, residential combustion of both biomass (referred to as “biofuel”) and coal is important, whereas across other parts of Asia and Africa residential combustion of biofuel is dominant (Lu et al., 2011; Bond et al., 2013).

Estimates of residential emissions are typically “bottom-up”, combining information on fuel consumption rates with laboratory or field emission factors. Obtaining reliable estimates of residential fuel use is difficult because these fuels are often collected by consumers and are not centrally recorded (Bond et al., 2013). Emission factors are hugely variable, depending on the type, size, and moisture content of fuel, as well as stove design, operation, and combustion conditions (Roden et al., 2006, 2009; Li et al., 2009; Shen

et al., 2010). As a result, uncertainty in residential emissions may be as large as a factor 2 or more (Bond et al., 2004). There is a range of evidence that residential emissions may be underestimated. Firstly, emission factors for RSF combustion derived from laboratory experiments are often less than those derived under ambient conditions (Roden et al., 2009). Secondly, models typically underestimate observed aerosol absorption optical depth, BC, and OC over regions associated with large RSF emissions such as in South and East Asia (Park et al., 2005; Koch et al., 2009; Ganguly et al., 2009; Menon et al., 2010; Nair et al., 2012; Fu et al., 2012; Moorthy et al., 2013; Bond et al., 2013; Pan et al., 2015). A further complication is that residential emissions, particularly from residential heating, also exhibit seasonal variability (Aunan et al., 2009; Stohl et al., 2013), but this is rarely implemented within global modelling studies.

Atmospheric aerosols interact with the Earth’s radiation budget directly through the scattering and absorption of solar radiation (direct radiative effect – DRE – or aerosol–radiation interactions) and indirectly by modifying the microphysical properties of clouds (aerosol indirect effect – AIE – or aerosol–cloud interactions) (Forster et al., 2007; Boucher et al., 2013). The interaction of aerosol with radiation and clouds depends on properties of the aerosol, including mass concentration, size distribution, chemical composition, and mixing state (Boucher et al., 2013). BC is strongly absorbing at visible and infrared wavelengths, exerting a positive DRE. BC particles coated with a non-absorbing shell have greater absorption compared to a fresh BC core due to a lensing effect (Fuller et al., 1999; Jacobson, 2001). More recent studies have shown that a fraction of organic aerosol can absorb light (Kirchstetter et al., 2004; Chen and Bond, 2010; Arola et al., 2011), with the light absorbing fraction termed “brown carbon”. The net DRE of residential combustion emissions is a complex combination of these warming and cooling effects.

Aerosol also impacts climate through altering the properties of clouds. The cloud albedo or first AIE is the radiative effect due to a change in cloud droplet number concentration (CDNC), assuming a fixed cloud water content. The change in CDNC is governed by the number concentration of aerosols that are able to act as cloud condensation nuclei (CCN), which is determined by aerosol size and chemical composition (Penner et al., 2001; Dusek et al., 2006). Modelling studies have shown the importance of carbonaceous combustion aerosols to global CCN concentrations (Pierce et al., 2007; Spracklen et al., 2011a) and modification of cloud properties (Bauer et al., 2010; Jacobson, 2010). However, there is considerable variability in the size of particles emitted by combustion sources including those from residential sources (Venkataraman and Rao, 2001; Shen et al., 2010; Pagels et al., 2013; Bond et al., 2006) that will impact simulated CCN concentrations (Pierce et al., 2007, 2009; Reddington et al., 2011; Spracklen et al., 2011a; Kodros et al., 2015) and AIE (Bauer et al., 2010; Spracklen et

al., 2011a; Kodros et al., 2015). Aerosols can further alter cloud properties through the second aerosol indirect effect and through semi-direct effects (Koch and Del Genio, 2010).

The net radiative effect (RE) of residential emissions depends on the fuel and combustion process (Bond et al., 2013). Carbonaceous emissions from residential biofuel exhibit higher POM:BC mass ratios compared to residential coal, which emits more BC and sulfur (Bond et al., 2013). Aunan et al. (2009) found that despite large BC emissions over Asia, RSF combustion emissions exerted a small net negative DRE because of co-emitted scattering aerosols; however, this study did not include aerosol–cloud effects. Jacobson (2010) reported increased cloud cover and depth from biofuel aerosol and gases as well as a net positive RE. In contrast, Bauer et al. (2010) found the negative AIE from residential biofuel combustion to be 3 times greater than the positive DRE, resulting in a negative net RE. Unger et al. (2010) used a mass-only aerosol model to calculate a positive AIE due to the residential sector. The review of Bond et al. (2013) identified a net negative RE (DRE and AIE) for biofuel with large uncertainty but a slight net positive RE (with low certainty) from residential coal (Bond et al., 2013). However, a recent detailed global modelling study found that the climate effects of residential biofuel combustion aerosol are largely unconstrained because of uncertainties in emission mass flux, emitted size distribution, optical mixing state, and ratio of BC to POM (Kodros et al., 2015)

In addition to impacting climate, aerosol from residential fuel combustion degrades air quality with adverse implications for human health. Epidemiologic research has confirmed a strong link between exposure to particulate matter (PM) and adverse health effects, including premature mortality (Pope III and Dockery, 2006; Brook et al., 2010). Exposure to PM<sub>2.5</sub> (PM with an aerodynamic dry diameter of < 2.5 μm) is thought to be particularly harmful to human health (Pope III and Dockery, 2006; Schlesinger et al., 2006). Household air pollution, mostly from RSF combustion (Smith et al., 2014) in low and middle income countries, is estimated to cause 4.3 million deaths annually (WHO, 2014a), making it one of the leading risk factors for global disease burden (Lim et al., 2012). Global estimates of premature mortality attributable to ambient (outdoor) air pollution range from 0.8 million to 3.7 million deaths per year, most of which occur in Asia (Cohen et al., 2005; Anenberg et al., 2010; WHO, 2014b). These estimates rely on PM<sub>2.5</sub> concentrations from coarse global models with mean spatial resolutions of ~200 km. At these resolutions, human health estimates are likely underestimated at urban and semi-urban scales. Emission inventories highlight residential combustion as one of the most important contributors to ambient PM<sub>2.5</sub>, accounting for 55 % in Europe (EEA, 2014) and 33 % in China (Lei et al., 2011). However, while previous studies have estimated the human health impacts from ambient air pollution due to fossil fuel combustion (Anenberg et al., 2010), open biomass burning (Johnston et al., 2012;

Marlier et al., 2013), and wind-blown dust (Giannadaki et al., 2014), fewer studies have quantified the impact of residential combustion on ambient quality and human health. Lim et al. (2012) estimated that 16 % of the global burden of ambient PM<sub>2.5</sub> was due to RSF sources but did not estimate premature mortality. Another study concluded that ambient PM<sub>2.5</sub> from cooking was responsible for 370 000 deaths in 2010 (Chafe et al., 2014), but it did not include residential heating emissions, which will cause additional adverse impacts on human health (Johnston et al., 2013; Allen et al., 2013; Y. Chen et al., 2013).

Here we use a global aerosol microphysics model to make an integrated assessment of the impact of residential emissions on atmospheric aerosol, radiative effect, and human health. We used a radiative transfer model to calculate the DRE and first AIE due to residential emissions. To improve our understanding of the health impacts associated with these emissions, we combined simulated PM<sub>2.5</sub> concentrations with concentration-response functions from the epidemiological literature to estimate excess premature mortality.

## 2 Methods

### 2.1 Model description

We used the GLOMAP global aerosol microphysics model (Spracklen et al., 2005a), which is an extension to the TOMCAT 3-D global chemical transport model (Chipperfield, 2006). We used the modal version of the model, GLOMAP-mode (Mann et al., 2010), where aerosol mass and number concentrations are carried in seven log-normal size modes: four hydrophilic (nucleation, Aitken, accumulation, and coarse) and three non-hydrophilic (Aitken, accumulation, and coarse) modes. The model includes size-resolved aerosol processes including primary emissions, secondary particle formation, particle growth through coagulation, condensation, and cloud-processing and removal by dry deposition, in-cloud, and below-cloud scavenging. The model treats particle formation from both binary homogenous nucleation (BHN) of H<sub>2</sub>SO<sub>4</sub>–H<sub>2</sub>O (Kulmala et al., 1998) and an empirical mechanism to simulate nucleation within the model boundary layer or boundary layer nucleation (BLN). The formation rate of 1 nm clusters (J1) within the BL is proportional to the gas-phase H<sub>2</sub>SO<sub>4</sub> concentration ([H<sub>2</sub>SO<sub>4</sub>]) to the power of 1 (Sihto et al., 2006; Kulmala et al., 2006) according to  $J1 = A[H_2SO_4]$ , where  $A$  is the nucleation rate coefficient of  $2 \times 10^{-6} \text{ s}^{-1}$  (Sihto et al., 2006). GLOMAP-mode simulates multi-component aerosol and treats the following components: sulfate, dust, BC, POM, and sea salt. Primary carbonaceous combustion particles (BC and POM) are emitted as a non-hydrophilic distribution (Aitken insoluble mode). Dust is emitted into the insoluble accumulation and coarse modes. Non-hydrophilic particles are transferred

into hydrophilic particles through coagulation and condensation processes. The model uses a horizontal resolution of  $2.8^\circ$  by  $2.8^\circ$  and 31 vertical levels between the surface and 10 hPa. Large-scale transport and meteorology is specified at 6 h intervals from the European Centre for Medium-Range Weather Forecasts (ECMWF) analyses interpolated to model timestep. All model simulations are for the year 2000, completed after a 3-month model spin up. Oxidants of OH,  $O_3$ ,  $H_2O_2$ ,  $NO_3$ , and  $HO_2$  are specified using 6 h mean offline concentrations from a TOMCAT simulation with detailed tropospheric chemistry (Arnold et al., 2005).

## 2.2 Emissions

The model uses gas-phase  $SO_2$  emissions for both continuous (Andres and Kasgnoc, 1998) and explosive (Halmer et al., 2002) volcanic eruptions. Open biomass burning emissions are from the Global Fire Emission Database (van der Werf et al., 2004). Oceanic dimethyl-sulfide (DMS) emissions are calculated using an ocean surface DMS concentration database (Kettle and Andreae, 2000) combined with a sea–air exchange parameterization (Nightingale et al., 2000). Emissions of sea salt were calculated using the scheme of Gong (2003). Biogenic emissions of terpenes are taken from the Global Emissions Inventory Activity database and are based on Guenther et al. (1995). Daily-varying dust emission fluxes are provided by AeroCom (Dentener et al., 2006).

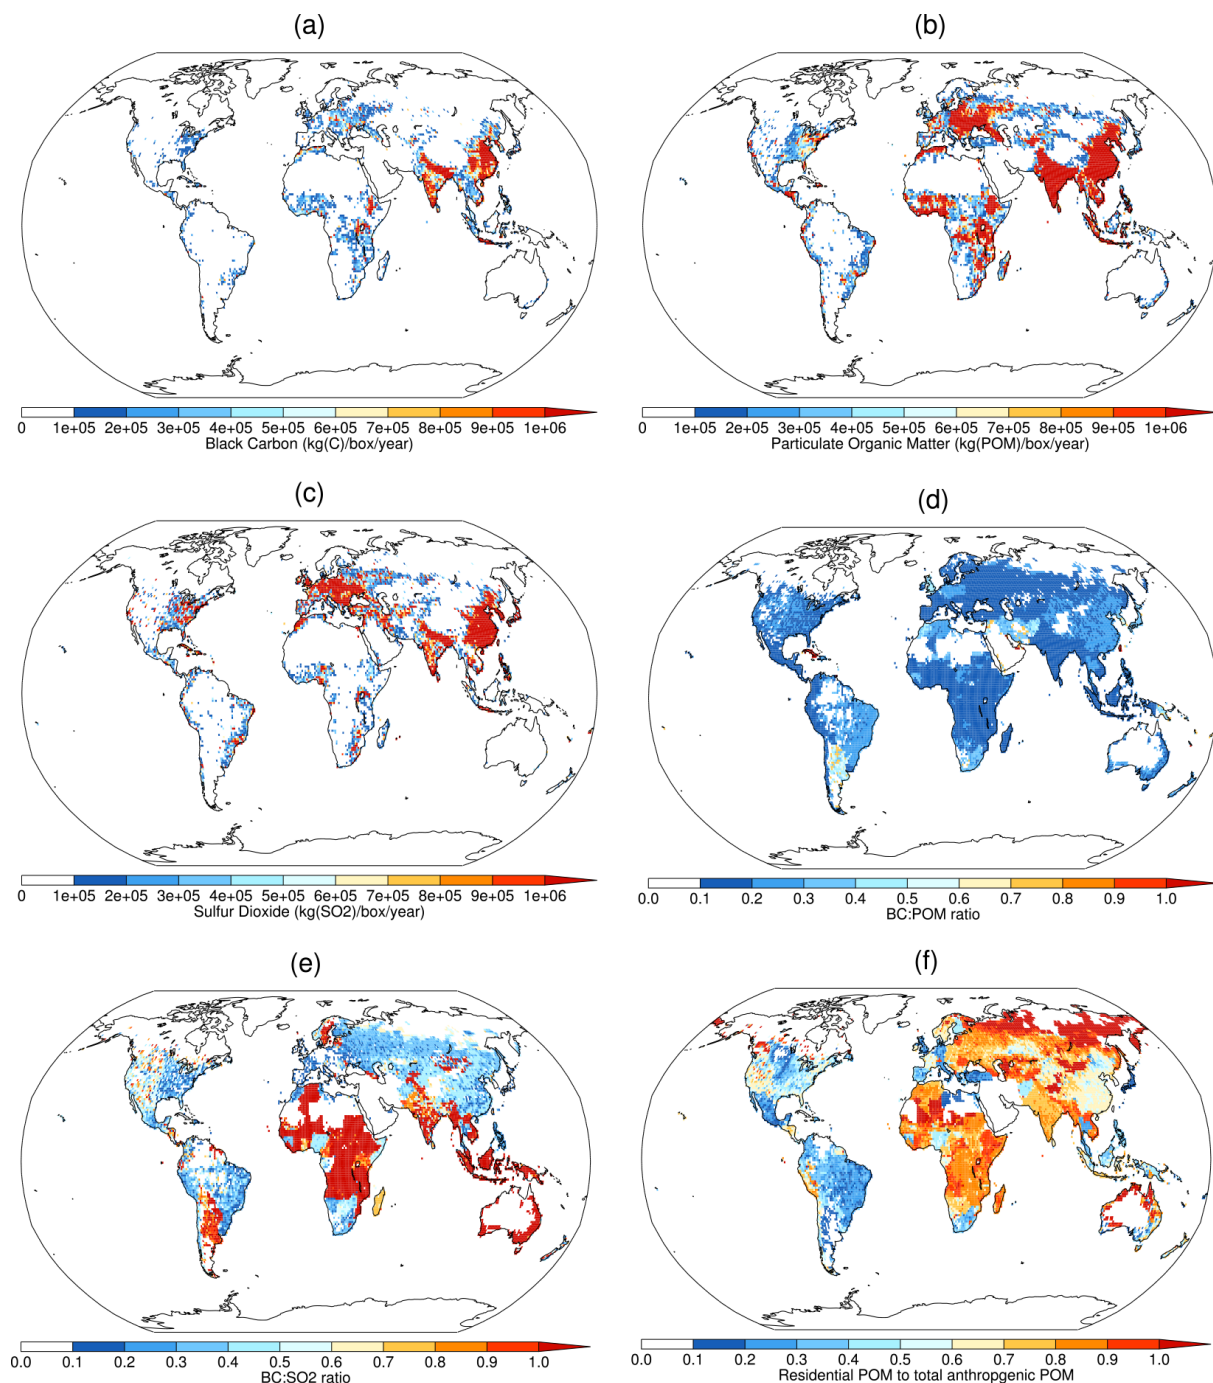

Annual mean anthropogenic emissions of gas-phase  $SO_2$  and carbonaceous aerosol for the year 2000 are taken from the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) (Lamarque et al., 2010). This data set includes emissions from energy production and distribution, industry, land transport, maritime transport, residential and commercial, and agricultural waste burning on fields. To test the sensitivity to anthropogenic emissions, we completed sensitivity studies (see Sect. 2.6) using anthropogenic emissions from the MACCity (MACC/CityZEN projects) emission data set for the year 2000 (Granier et al., 2011). MACCity emissions are derived from ACCMIP and apply a monthly varying seasonal cycle for anthropogenic emissions (Granier et al., 2011). In both emissions data sets, anthropogenic carbonaceous emissions are based on the Speciated Particulate Emissions Wizard (SPEW) inventory (Bond et al., 2007). In GLOMAP, anthropogenic carbonaceous emissions are added to the lowest model layer, while open biomass burning emissions are emitted between the surface and 6 km (Dentener et al., 2006).

We isolate the impact of residential fuel combustion through simulations where we switch off emissions from the “residential and commercial” sector. The term “residential” includes emissions from household activities, while “commercial” refers to emissions from commercial business activities (excluding agricultural activities). Both residential and commercial activities use similar fuels for similar purposes, but because emissions are dominated by residential activi-

ties, we refer to the “residential and commercial” sector collectively as the “residential” sector. Residential fuels used in small-scale combustion for cooking, heating, lighting, and auxiliary engines, consist of many different types such as RSFs (biomass/biofuel and coal) and hydrocarbon-based fuels including kerosene, liquefied petroleum gas, gasoline, and diesel. The ACCMIP and MACCity residential data sets do not allow us to isolate the impacts of different RSFs separately from other residential hydrocarbon-based fuels, but according to the results from the Greenhouse Gas and Air Pollution Interactions and Synergies (GAINS) model, typically  $\geq 90\%$  of PM emissions can be attributed to RSFs within most regions, of which a large proportion is from biomass sources. Compared with residential hydrocarbon-based fuels, RSFs typically burn at lower combustion efficiencies, resulting in substantially higher aerosol emissions (Venkataraman et al., 2005). Residential kerosene wick lamps can produce substantial emissions (Lam et al., 2012); however, these are not included in the ACCMIP and MACCity data sets. Residential biofuel and coal emissions from ACCMIP and MACCity differ to previous global emission inventories (Bond et al., 2004, 2007) through the incorporation of updated emissions factors from field measurements (Roden et al., 2006, 2009; Johnson et al., 2008) and laboratory experiments for biofuel sources in India (Venkataraman et al., 2005; Parashar et al., 2005) and residential coal sources in China (Chen et al., 2005, 2006; Zhi et al., 2008). In both the ACCMIP and MACCity emission data sets, global emissions for the residential and commercial sectors are BC ( $\sim 1.9 \text{ Tg yr}^{-1}$ ), POM ( $\sim 11.0 \text{ Tg POM yr}^{-1}$ ), and  $SO_2$  ( $\sim 8.3 \text{ Tg } SO_2 \text{ yr}^{-1}$ ).

Figure 1 shows the spatial distribution of BC, POM, and  $SO_2$  emissions from the residential sector in the ACCMIP data set (Lamarque et al., 2010). Residential emissions are greatest over densely populated regions of Africa and Asia where infrastructure and income do not allow access to clean sources of residential energy. The dominant fuel type varies spatially resulting in distinct patterns in pollutant emission ratios (Fig. 1d–e). Residential emissions are dominated by biofuel (biomass) combustion in sub-Saharan Africa, South Asia, and parts of Southeast Asia and characterised by low BC:POM and high BC: $SO_2$  ratios. Residential coal combustion is more important in parts of Eastern Europe, the Russian Federation, and East Asia, characterised by higher BC:POM and lower BC: $SO_2$  ratios. In the ACCMIP and MACCity data sets, residential sources account for 38% of global total anthropogenic BC and 61% of total global anthropogenic POM emissions. The regional contribution of residential emissions can be even greater (Fig. 1f). For China, residential emissions represent 40% of anthropogenic BC and 60% of anthropogenic POM emissions. In India, residential emissions represent 63% of anthropogenic BC and 78% of anthropogenic POM emissions.

We assume primary particles from combustion sources are emitted with a fixed log-normal size distribution with a specified geometric mean diameter ( $D$ ) and standard de-

**Figure 1.** Annual residential emissions from the ACCMIP emission data set for BC (a), POM (b), SO<sub>2</sub> (c), BC : POM ratio (d), BC : SO<sub>2</sub> ratio (e), and residential POM to total anthropogenic POM (f).

variation ( $\sigma$ ). Assumptions regarding  $D$  and  $\sigma$  for each experiment are detailed in the footnotes of Table 2. This assumption accounts for both the size of primary particles at the point of emission and the sub-grid-scale dynamical processes that contribute to changes in particle size and number concentrations at short timescales after emission (Pierce and Adams, 2009; Reddington et al., 2011). Subsequent aging

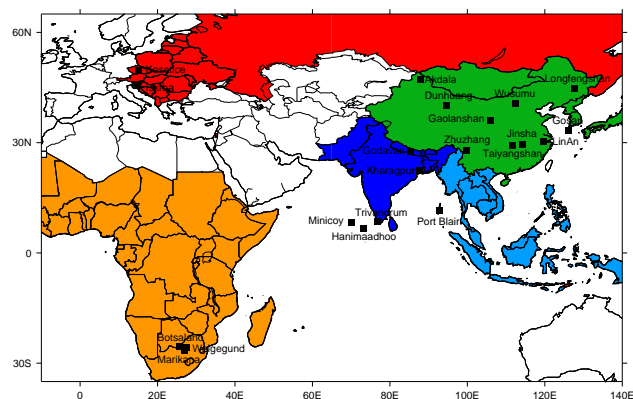

and growth of the particles are determined by microphysical processes such as coagulation, condensation, and cloud processing simulated by the model. We assume that 2.5 % of SO<sub>2</sub> from anthropogenic and volcanic sources is emitted as primary sulfate particles.

### 2.3 In situ measurements

To evaluate our model, we synthesised in situ measurements of BC, OC, and  $PM_{2.5}$  concentrations, aerosol number size distribution, and estimates of the contribution of biomass derived BC from  $^{14}C$  analysis. GLOMAP has been evaluated for locations in North America (Mann et al., 2010; Spracklen et al., 2011a), the Arctic (Browse et al., 2012; Reddington et al., 2013), and Europe (Schmidt et al., 2011). Here, we focus our evaluation at locations that may be strongly influenced by residential emissions (Fig. 1) and where the model has not been previously evaluated. We focus on rural and background locations because these are more appropriate for comparison to global models with coarse spatial resolutions.

Figure 2 shows the locations of observations used in this study. Information on the measurements for each location is reported in Table 1. Note that the coloured geographical regions in Fig. 2 are only used to distinguish differences in mortality across different regions (see Sect. 3.3). The technique and instruments used to measure BC and OC vary across the different sites (see Table 1). Thermal–optical techniques measure elemental carbon (EC) whereas optical techniques measure BC. Previous studies have documented systematic differences between these techniques but concluded that measurement uncertainties are generally larger than the differences between the measurement techniques (Bond et al., 2004, 2007). We therefore treat different measurement techniques identically and consider EC and BC to be equivalent. For sites in Eastern Europe, we used BC and OC mass concentrations from the Czech Republic and Slovenia (Table 1). For sites in South Africa, we used  $PM_{2.5}$  and BC mass and aerosol number size distribution (Vakkari et al., 2013). For sites in South Asia, we used BC mass from the Integrated Campaign for Aerosols gases and Radiation Budget (ICARB) field campaign at eight locations across the Indian mainland and islands (Moorthy et al., 2013). For South Asian sites, we also used  $PM_{2.5}$ , EC, and OC mass, aerosol number size distribution from the island of Hanimaadhoo in the Maldives (Stone et al., 2007), and EC and OC measurements from Godavari in Nepal (Stone et al., 2010). For sites in East Asia, we used EC and OC mass data compiled by Fu et al. (2012) for two background (Qu et al., 2008) and seven rural sites (Zhang et al., 2008; Han et al., 2008) in China, while measurements from Gosan, South Korea, were taken from Stone et al. (2011). Few long-term observations of CCN are available, so instead we use the number concentration of particles greater than 50 nm dry diameter ( $N_{50}$ ) and 100 nm ( $N_{100}$ ) as a proxy for CCN number concentrations. We calculated  $N_{50}$  and  $N_{100}$  concentrations from aerosol number size distribution measurements at Hanimaadhoo, Botsalano, Marikana, and Welgegund (see Table 1). We note this approach does not account for the impact of particle composition on CCN activity.

We also use information on BC fossil and non-fossil fractions as obtained from three separate source apportionment

**Figure 2.** Locations of aerosol measurements used in this study and geographical regions of Eastern Europe and the Russian Federation (red), Africa (orange), South Asia (dark blue), Southeast Asia (light blue), and East Asia (green). Note that geographical regions are only used to distinguish difference in mortality across different regions (see Sect. 3.3).

studies (Gustafsson et al., 2009; Sheesley et al., 2012; Bosch et al., 2014) that use  $^{14}C$  analysis of carbonaceous aerosol taken at Hanimaadhoo in the Indian Ocean. This technique determines the fossil and non-fossil fractions of carbonaceous aerosol, since  $^{14}C$  is depleted in fossil fuel aerosol (half-life 5730 years), whereas non-fossil aerosol (e.g. bio-fuel, open biomass burning, and biogenic emissions) shows a contemporary  $^{14}C$  content. As previously mentioned, residential emissions consist of a mixture of both fossil and non-fossil sources, with a greater proportion coming from the former. To make distinctions on the fossil versus non-fossil fraction of residential BC emissions, we make assumptions based on information from other emission inventories and models over the South Asian region (see Sect. 3.2 for more details).

### 2.4 Calculating health effects

We calculate annual excess premature mortality from exposure to ambient  $PM_{2.5}$  using concentration response functions (CRFs) from the epidemiological literature that relate changes in  $PM_{2.5}$  concentrations to the relative risk (RR) of disease. CRFs are uncertain and have been previously based on the relationship between RR and  $PM_{2.5}$  concentrations using either a log-linear model (Ostro, 2004) or a linear model (Cohen et al., 2004). These CRFs were based on the American Cancer Society Prevention cohort study, where observed annual mean  $PM_{2.5}$  concentrations were typically below  $30 \mu\text{g m}^{-3}$ . The log-linear model was recommended by the WHO for use in ambient air pollution burden of disease estimates at the national level (Ostro, 2004) due to the concern that linear models would produce unrealistically large RR estimates when extrapolated to higher  $PM_{2.5}$  concentrations above that of  $30 \mu\text{g m}^{-3}$ . The log-linear models have been used in various modelling studies (Anenberg et al.,

Table 1. Summary of aerosol observations used in this study.

Region and measurement location/site name	Site description	Measurement	Measurement period	Measurement technique	Reference
Eastern European sites

\* Data obtained through the EBAS atmospheric database (<http://ebas.mtu.no/Default.aspx>).

2010; Schmidt et al., 2011; Partanen et al., 2013; Reddington et al., 2015). More recent models have been proposed to relate disease burden to different combustion sources in order to capture RR over a larger range of  $\text{PM}_{2.5}$  concentrations up to  $300 \mu\text{g m}^{-3}$  (Burnett et al., 2014). However, given that we use a global model with relatively coarse spatial resolution where  $\text{PM}_{2.5}$  concentrations very rarely exceed  $100 \mu\text{g m}^{-3}$ , we employ the log-linear model of Ostro (2004). We calculate RR for cardiopulmonary diseases and lung cancer following Ostro (2004):

$$\text{RR} = \left[ \frac{(\text{PM}_{2.5,\text{control}} + 1)}{(\text{PM}_{2.5,\text{R\_off}} + 1)} \right]^\beta, \quad (1)$$

where  $\text{PM}_{2.5,\text{control}}$  is annual mean simulated  $\text{PM}_{2.5}$  concentrations of the control experiments and  $\text{PM}_{2.5,\text{R\_off}}$  is a perturbed experiment where residential emissions have been removed. The cause-specific coefficient ( $\beta$ ) is an empirical parameter with separate values for lung cancer (0.23218, 95 % confidence interval of 0.08563–0.37873) and cardiopulmonary diseases (0.15515, 95 % confidence interval of 0.05624–0.2541). To calculate the disease burden attributable to the RR, known as the attributable fraction (AF), we follow Ostro (2004):

$$\text{AF} = (\text{RR} - 1)/\text{RR}. \quad (2)$$

To calculate the number of excess premature mortality in adults over 30 years of age, we apply AF to the total number of recorded deaths from the diseases of interest:

$$\Delta M = \text{AF} \times M_0 \times P_{30+}, \quad (3)$$

where  $M_0$  is the baseline mortality rate for each disease risk and  $P_{30+}$  is the exposed population over 30 years of age. We only calculate premature mortality for persons over the age of 30 years because this fraction of the population is more susceptible to cardiopulmonary disease and lung cancer. We use country-specific baseline mortality rates from the WHO “The global burden of disease: 2004 update” (Mathers et al., 2008) for the year 2004 and human population data from the Gridded World Population (GWP, version 3) project (SEDAC, 2004) for the year 2000.

## 2.5 Calculating radiative effects

We quantified the DRE and first AIE of residential emissions using an offline radiative transfer model (Edwards and Slingo, 1996). With nine radiation bands in the longwave (LW) and six bands in the shortwave (SW). We use a monthly mean climatology of water vapour, temperature, and ozone based on ECMWF reanalysis data, together with surface albedo and cloud fields from the International Satellite Cloud Climatology Project (ISCCP-D2) (Rossow and Schiffer, 1999) for the year 2000.

Following the methodology described in Rap et al. (2013) and Scott et al. (2014), we estimate the DRE using the

radiative transfer model to calculate the difference in net (SW + LW) top-of-atmosphere (TOA) all-sky radiative flux between model simulations with and without residential emissions. A refractive index is calculated for each individual mode separately, as the volume-weighted mean of the refractive indices for the individual components (including water) present (given at 550 nm in Table A1 of Bellouin et al., 2011). Coefficients for absorption and scattering, and asymmetry parameters, are then obtained from look-up tables containing all realistic combinations of refractive index and Mie parameter (particle radius normalised to the wavelength of radiation), as described by Bellouin et al. (2013). The assumption that BC is internally or homogeneously mixed with scattering species is unrealistic, providing an upper bound for DRE (Jacobson, 2001; Kodros et al., 2015).

To determine the first AIE we calculate the contribution of residential emissions to CDNC. We calculate CDNC using the parameterisation of cloud drop formation (Nenes and Seinfeld, 2003; Fountoukis and Nenes, 2005; Barahona et al., 2010) as described by Pringle et al. (2009). The maximum supersaturation ( $\text{SS}_{\text{max}}$ ) of an ascending cloud parcel depends on the competition between increasing water vapour saturation with decreasing pressure and temperature and the loss of water vapour through condensation onto activated particles. Monthly mean aerosol size distributions are converted to a supersaturation distribution where the number of activated particles can be determined for the  $\text{SS}_{\text{max}}$ . CDNC are calculated using a constant up-draught velocity of  $0.15 \text{ ms}^{-1}$  over sea and  $0.3 \text{ ms}^{-1}$  over land, which is consistent with observations for low-level stratus and stratocumulus clouds (Pringle et al., 2012). In reality, up-draught velocities vary, but the use of average velocities in previous GLOMAP studies has been shown to capture observed relationships between particle number and CDNC (Pringle et al., 2009), as well as reproducing realistic CDNC (Merikanto et al., 2010). The AIE is calculated using the methodology described previously (Spracklen et al., 2011a; Schmidt et al., 2012; Scott et al., 2014) where a control uniform cloud droplet effective radius  $r_{e1} = 10 \mu\text{m}$  is assumed to maintain consistency with the ISCCP determination of liquid water path. For each perturbation experiment the effective radius  $r_{e2}$  is calculated:

$$r_{e2} = r_{e1} \times (\text{CDNC}_1/\text{CDNC}_2)^{\frac{1}{3}}, \quad (4)$$

where  $\text{CDNC}_1$  represents a control simulation including residential emissions and  $\text{CDNC}_2$  represents a simulation where residential emissions have been removed. The AIE is calculated by comparing the net TOA radiative fluxes using the different  $r_{e2}$  values derived for each perturbation experiment, to that of the control where  $r_{e1}$  is fixed. We do not calculate the cloud lifetime (second indirect effect), semi-direct effects, or snow albedo changes. We also do not account for light absorbing brown carbon and the lensing effect of BC particles coated with a non-absorbing shell, and thus we are

unable to estimate the full climate impact of residential combustion emissions.

## 2.6 Model simulations

Table 2 reports the model experiments used in this study. These simulations explore uncertainty in residential emission flux and emitted carbonaceous aerosol size distributions and the impact of particle formation. We test two different emission data sets (see Sect. 2.2 for details) allowing us to explore the role of seasonally varying emissions compared to annual mean emissions. We refer to the simulation using the ACCMIP emissions (annual mean emissions) with the standard model setup as the baseline simulation (*res\_base*), while all other simulations explore key uncertainties relative to *res\_base* or use the MACCity emission database of monthly varying anthropogenic emissions (*res\_monthly*). To allow us to quantify the impact of residential emissions we conduct simulations where residential emissions (BC, OC and SO<sub>2</sub>) have been switched off (*res\_base\_off* and *res\_monthly\_off*). To account for uncertainties in the nucleation scheme, we conduct simulations where only BHN is able to contribute to new particle formation (*res\_BHN* and *res\_BHN\_off*), while all other simulations include both BHN and BLN. For the majority of our simulations, we use *D* and  $\sigma$  recommended by Stier et al. (2005) (*D* = 150 nm  $\sigma$  = 1.59). To account for the uncertainty in the size of emitted residential carbonaceous combustion aerosol and uncertainty of sub-grid ageing of the size distribution, we conduct simulations spanning the range of observed size distributions for primary BC and OC residential combustion particles, while keeping emission mass fixed. We use AeroCom (Dentener et al., 2006) recommended particle size settings (*res\_aero*) (*D* = 80 nm  $\sigma$  = 1.8) and, following a similar approach to Bauer et al. (2010), we use the range identified by Bond et al. (2006) for lower (*res\_small*) (*D* = 20 nm  $\sigma$  = 1.8) and upper (*res\_large*) (*D* = 500 nm  $\sigma$  = 1.8) estimates. To account for possible low biases in residential emission flux, we conduct simulations where residential primary carbonaceous combustion aerosol mass (BC and OC) are doubled relative to the baseline simulation (*res\_x2*) and the simulation using monthly mean anthropogenic emissions (*res\_monthly\_x2*). We also perform experiments where only residential BC and OC emissions are doubled separately relative to the baseline simulation (*res\_BCx2* and *res\_POMx2*) to explore uncertainties in both emission mass flux and emission ratio. While the uncertainties in primary carbonaceous aerosol emissions are thought to be higher than for gas-phase SO<sub>2</sub> (Klimont et al., 2009), we also conduct an experiment where we double residential SO<sub>2</sub> emissions (*res\_SO2x2*).

## 3 Results

### 3.1 Model evaluation

Figure 3 compares observed and simulated monthly mean BC, OC, and PM<sub>2.5</sub> concentrations and normalised mean bias factor (NMBF) (Yu et al., 2006), where  $M_i$  are the simulated concentrations by the model and  $O_i$  are the observed concentrations at each measurement location, *i*,

$$\begin{aligned} \text{NMBF} &= \frac{\sum (M_i - O_i)}{\sum O_i} \text{ if } \bar{M} \geq \bar{O} \text{ and} \\ \text{NMBF} &= \frac{\sum (M_i - O_i)}{\sum M_i} \text{ if } \bar{M} < \bar{O}. \end{aligned} \quad (5)$$

The baseline simulation underestimates observed BC (NMBF = -2.33), OC (NMBF = -5.02), and PM<sub>2.5</sub> (NMBF = -1.33) concentrations. The greatest model underprediction is across East Asia (BC: NMBF = -2.61, OC: NMBF = -6.56, and PM<sub>2.5</sub>: NMBF = -1.94). Over South Asia the model is relatively unbiased against OC (NMBF = 0.41) but underestimates BC (NMBF = -2.54). In contrast, over Eastern Europe the model is unbiased against BC (NMBF = 0.01) but underestimates OC (NMBF = -2.63). The simulation with monthly varying emissions compares slightly better with observations compared to the baseline simulation but still underestimates BC (NMBF = -2.29), OC (NMBF = -4.92), and PM<sub>2.5</sub> (NMBF = -1.34), suggesting that seasonality in emissions has little impact on reducing model bias. The low bias in our model, particularly for BC and OC, is consistent with previous modelling studies using bottom-up emission inventories in South Asia (Ganguly et al., 2009; Menon et al., 2010; Nair et al., 2012; Moorthy et al., 2013; Pan et al., 2015) and East Asia (Park et al., 2005; Koch et al., 2009; Fu et al., 2012). The contribution of residential emissions is illustrated by the model simulation where these emissions are switched off, with substantially greater underestimation of BC (NMBF = -5.12), OC (NMBF = -11.46), and PM<sub>2.5</sub> (NMBF = -1.60) concentrations (Fig. 3d). Doubling residential carbonaceous emissions improves model agreement with observations, but the model still underestimates BC (NMBF = -1.33), OC (NMBF = -2.96), and PM<sub>2.5</sub> (NMBF = -1.17) concentrations.

Figure 4 compares observed and simulated concentrations for South Asian locations. The baseline simulation underestimates carbonaceous aerosol concentrations at all locations, although there is better agreement at Godavari and Hanimaadhoo. BC measurements at these two sites were made through thermal-optical methods, whereas other locations in South Asia used optical methods (Table 1). Different measurement techniques result in different mass concentrations (Stone et al., 2007) and may contribute to model-observation errors. The emission inventory that we use is based on carbonaceous measurements using thermal-optical

**Table 2.** Summary of model simulations and global annual mean values and changes to BC and POM burden, continental surface PM<sub>2.5</sub>, surface total particle number ( $N_3$ , diameter > 3 nm),  $N_{50}$  (diameter > 50 nm), low-cloud level (850–900 hPa) CDNC concentrations (0.15 and 0.3 ms<sup>-1</sup> cloud updraft velocity over sea and land respectively), and all-sky DRE and first AIE, relative to an equivalent experiment where residential emissions have been removed. We estimate annual global mortality for cardiopulmonary disease (CPD) and lung cancer (LC) following Ostro (2004) showing 95 % confidence interval (total in bold). Emissions used are either the ACCMIP data set (A) or the MACCity data set (M) with perturbations to residential emissions applied as detailed. For emitted carbonaceous size distributions, see Table footnote.

<sup>a</sup> Sier et al. (2005) recommended residential (biomass/hoofed) primary carbonaceous particle sizes:  $D = 150$  nm,  $\sigma = 1.59$ . <sup>b</sup> AeroCam (Dentener et al., 2006) recommended residential (biomass/hoofed) primary carbonaceous particle sizes:  $D = 80$  nm,  $\sigma = 1.8$ . <sup>c</sup> Observed lower bound limit for RSF primary carbonaceous particle sizes:  $D = 20$  nm,  $\sigma = 1.8$  (Bond et al., 2006). <sup>d</sup> Observed upper bound limit for RSF primary carbonaceous particle sizes:  $D = 500$  nm,  $\sigma = 1.8$  (Bond et al., 2006).

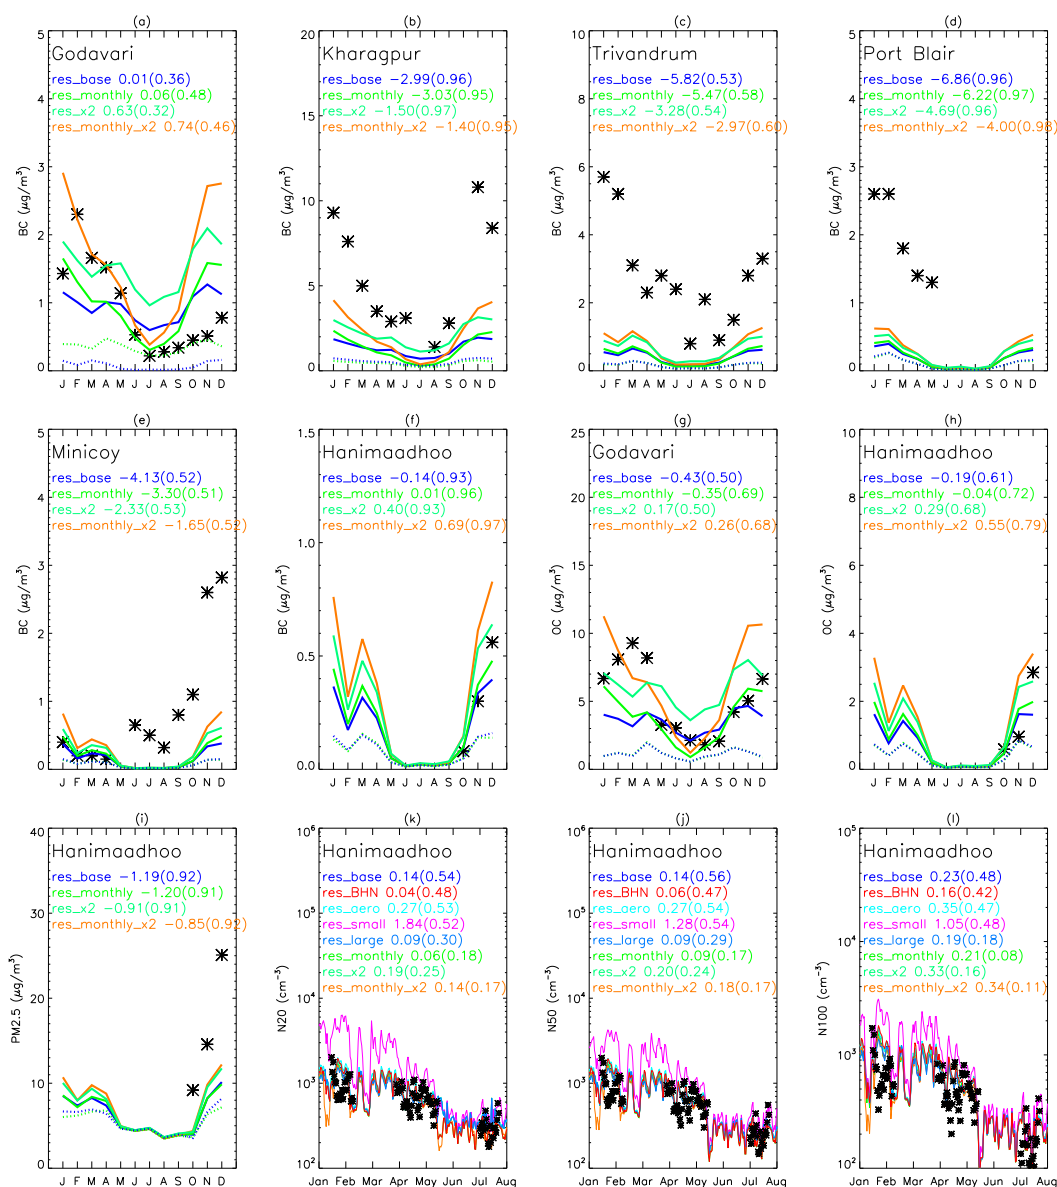

**Figure 3.** Observed and simulated monthly mean BC (a), OC (b), and PM<sub>2.5</sub> (c) concentrations for the baseline simulation (res\_base) using ACCMIP emissions at each measurement location depicted in Table 1 and normalised mean bias factor (NMBF) for each region defined in Table 1. (d) NMBF where square shows the baseline simulation, bottom error bar shows the range for removed residential emissions (res\_base\_off), and top error bar shows residential carbonaceous emissions doubled (res\_x 2) for each region defined in Table 1. Colours represent observed, simulated, and NMBF for measurement location regions defined in Table 1: all measurement locations (All: black), South Asian locations (SAsia: blue), East Asian locations (EAsia: green), Eastern European locations (EEurope: red), and South African locations (SAfrica: orange).

methods (Bond et al., 2004), which might explain the better agreement at Godavari and Hanimaadho. Doubling residential carbonaceous emissions improves the comparison against observations but leads to slight overestimation at Godavari and Hanimaadho. Pan et al. (2015) found that seven different global aerosol models underpredicted observed BC by up to a factor 10, suggesting that anthropogenic emissions are underestimated in these regions.

Observed BC and OC concentrations show strong seasonal variability, with lower concentrations during the summer monsoon period (June–September). The baseline simulation generally captures this seasonality relatively well (correlation coefficient between observed and simulated monthly mean concentrations  $r > 0.5$  at most sites), with minimal improvement with monthly varying anthropogenic emissions. This suggests that meteorological conditions such as enhanced wet deposition during the summer monsoon period are the dominant drivers for the observed and simulated seasonal variability, consistent with other modelling studies for the same region (Adhikary et al., 2007; Moorthy et al., 2013). Model simulations where residential emissions have been switched off show that residential combustion contributes

about two-thirds of simulated BC and OC at these locations. Figure 4k–l show a comparison of observed and simulated aerosol number concentrations at Hanimaadho. At this location, the baseline simulation simulates  $N_{20}$  (NMBF = 0.14),  $N_{50}$  (NMBF = 0.14) and  $N_{100}$  (NMBF = 0.24) concentrations well. Simulated number concentrations are sensitive to emitted particle size. Emitting residential primary carbonaceous emissions at very small sizes (res\_small) results in an overestimation of  $N_{20}$  (NMBF = 1.84),  $N_{50}$  (NMBF = 1.28) and  $N_{100}$  (NMBF = 1.05), suggesting that this assumption is unrealistic.

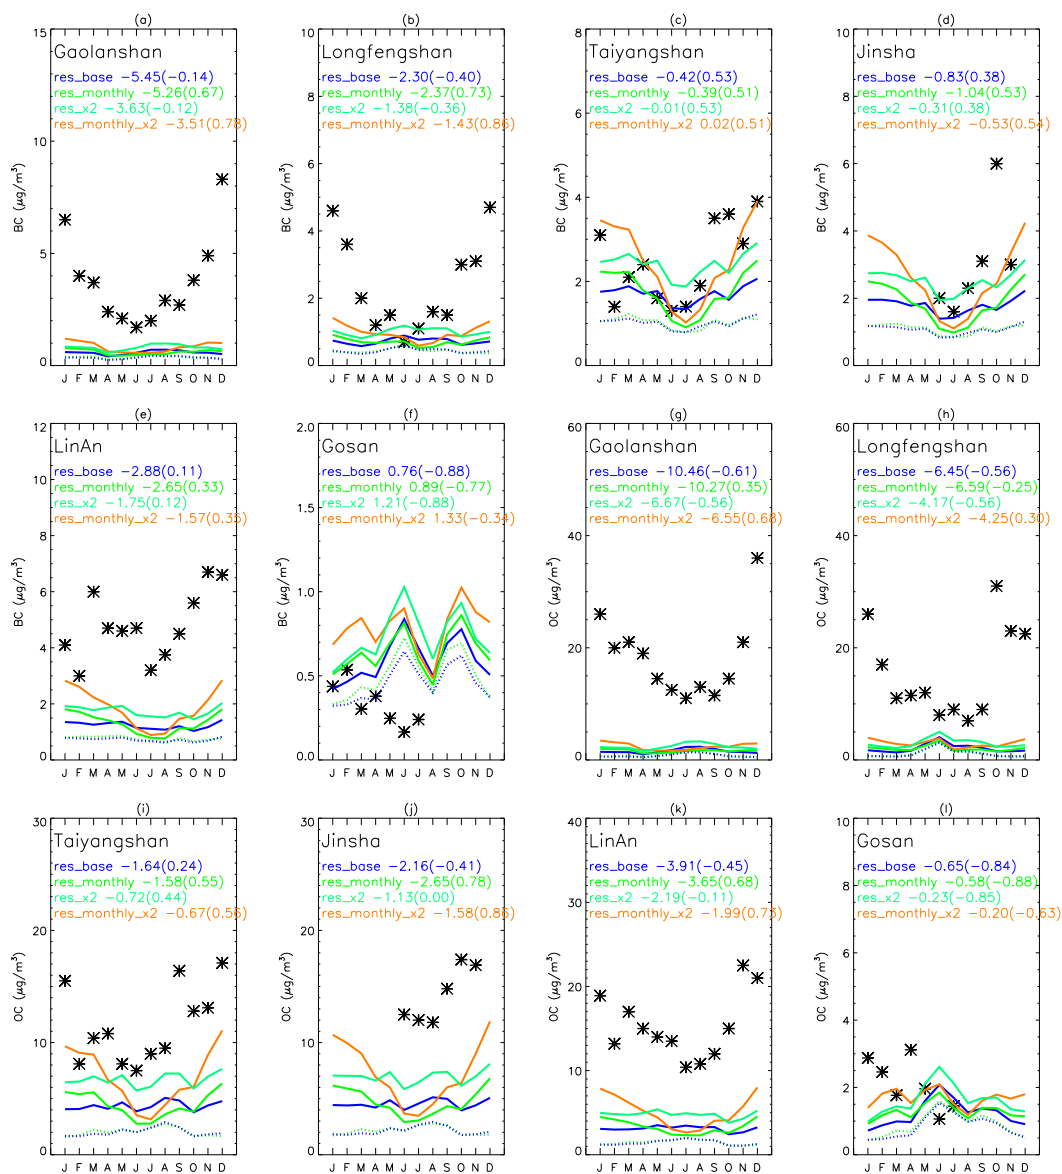

Figure 5 compares observed and simulated surface monthly mean BC and OC concentrations for East Asian locations. Observed surface BC and OC concentrations are generally enhanced during winter (December–February) compared to the summer (June–August). At all locations, the model underestimates BC (except for Gosan) and OC concentrations. The baseline simulation underpredicts both BC (NMBF < -2) and OC (NMBF < -6) at Gaolan Shan and Longfengshan (as well as Akdala, Dunhuang, and Wusumu, which are not shown in Fig. 5), which is consistent with a previous model study at these locations (Fu et al., 2012).

**Figure 4.** Observed (black stars) and simulated monthly mean BC (a–f), OC (g–h),  $\text{PM}_{2.5}$  (i), and daily mean  $N_{20}$  (k),  $N_{50}$  (j), and  $N_{100}$  (l) at South Asian locations. Normalised mean bias factor (NMBF) and correlation coefficient ( $r$ ) are reported for each model simulation:  $\text{NMBF}(r)$ . Experiments where residential emissions have been removed are represented by the blue ( $\text{res\_base\_off}$ ) and green ( $\text{res\_monthly\_off}$ ) dotted lines. Note that additional experiments ( $\text{res\_BHN}$ ,  $\text{res\_aero}$ ,  $\text{res\_small}$ , and  $\text{res\_large}$ ) are included in (k)–(i) because these experiments have little impact on aerosol mass (a–j).

The substantial underestimation at some locations (e.g. Dunhuang, Gaolan Shan, and Wusumu) may be due to local particulate sources that are not resolved by coarse model resolution. If we exclude these locations, NMBF improves for BC (−2.61 to −1.34) and OC (−4.43 to −3.29) for the East Asian region. The model better simulates BC ( $\text{NMBF} < -1$ ) and OC ( $\text{NMBF} < -2$ ) at Taiyangshan and Jinsha, although the model is still biased low. The baseline simulation, without seasonally varying emissions, fails to capture the observed seasonal variability in East Asia, with negative correlations

between observed and simulated aerosol concentrations at a number of locations. Fu et al. (2012) suggests that residential emissions (most likely heating sources) were the principle driver of simulated seasonal variability of EC (BC) at these locations. Implementing monthly varying anthropogenic emissions (including residential emissions) generally improves the simulated seasonal variability ( $r > 0.3$  at most sites) compared to using annual mean emissions. Doubling residential carbonaceous emissions also leads to improved NMBF at most locations. Residential emissions typi-

**Figure 5.** Observed (black stars) and simulated monthly mean BC (a–f) and OC (g–l) at East Asian locations. Normalised mean bias factor (NMBF) and correlation coefficient ( $r$ ) are reported for each model simulation: NMBF( $r$ ). Experiments where residential emissions have been removed are represented by the blue (res\_base\_off) and green (res\_monthly\_off) dotted lines.

cally account for 50–65 % of simulated BC and OC concentrations at these locations.

Figure 6 compares simulated and observed aerosol at South African and Eastern European locations. Marikana, Botsalano, and Welgegend are all located within the same region of South Africa and are influenced by both residential emissions and open biomass burning during the dry season, of which open biomass burning savannah fire seasonality peaks in July–September (Venter et al., 2012; Vakkari et al., 2013). Simulated aerosol number concentrations ( $N_{20}$  and  $N_{100}$ ) are underestimated at Marikana, consistent with the underprediction in BC at the same lo-

cation, while number concentrations are better simulated at Botsalano and Welgegend. The model underprediction at Marikana is likely due to the location being closer to emission sources, compared to Botsalano and Welgegend. For  $N_{100}$  the model is generally good at simulating open biomass savannah burning seasonality (peaking in August–September), but increases in observed  $N_{100}$  earlier in the season (May–August at Marikana and July at Welgegend) are not simulated. At both locations this early season maxima is likely due to residential emissions (Vakkari et al., 2013), which suggests that residential emissions are underrepresented in the model possibly due to resolution effects.

**Figure 6.** Observed (black stars) and simulated monthly mean  $N_{20}$  (a–c),  $N_{100}$  (d–f),  $PM_{2.5}$  (g), BC (h–k), and OC (j–l) at South African and Eastern European locations. Normalised mean bias factor (NMBF) and correlation coefficient ( $r$ ) are reported for each model simulation: NMBF( $r$ ). Experiments where residential emissions have been removed are represented by the blue (res\_base\_off) and green (res\_monthly\_off) dotted lines. Note that additional experiments (res\_BHN, res\_aero, res\_small, and res\_large) are included in (a)–(f) because these experiments have little impact on aerosol mass (g–i).

Aerosol number concentrations at Botsalano (NMBF = 0.47 to 1.01) and Welgegund (NMBF = 0.55 to 2.81) are overestimated when primary carbonaceous particles are emitted at the smallest size (res\_small), matching comparisons in South Asia and further suggesting that this assumption is unrealistic. The baseline simulation underestimates BC at Marikana (NMBF = −2.38) and  $PM_{2.5}$  concentrations at Botsalano (NMBF = −0.88), with a reduction in BC bias when residential carbonaceous emissions are doubled (NMBF = −1.62). At both these locations the model simulates a reasonable seasonality even without monthly varying residential emissions

( $r > 0.7$ ), possibly due to strong seasonality in open biomass savannah burning emissions.

Similar to other locations, observed BC and OC concentrations in Eastern Europe (Fig. 6i–l) are enhanced during winter (December–February). The baseline simulation performs well at simulating BC at Košetice (NMBF = +0.07) and Iskrba (NMBF = −0.14) but underestimates OC at Košetice (NMBF = −2.21) and Iskrba (NMBF = −3.27). Model agreement does not improve much when monthly varying anthropogenic emissions are used. The model performs bet-

**Figure 7.** Percentage contribution of residential emissions to annual surface mean  $PM_{2.5}$  (a), BC (b), POM (c), and sulfate ( $SO_4$ ) (d) concentrations (in size fraction  $PM_{2.5}$ ) for the baseline simulation (res\_base), relative to an equivalent simulation where residential emissions have been removed (res\_base\_off).

ter when residential carbonaceous emissions are doubled, but overestimates BC at Košetice.

In summary, we find the model typically underestimates observed BC and OC mass concentrations, which matches results from previous studies. Doubling residential emissions improves comparison against BC and OC observations, although the model is still typically biased low. To explore this further, we use  $^{14}C$  analysis (Sect. 3.2) to evaluate the contribution of residential emissions to carbonaceous aerosol. In general, the model compares better against observations of particle number, except when carbonaceous particles are emitted at small sizes leading to large overestimates in particle number.

### 3.2 Contribution of residential emissions to PM concentrations

Figure 7 shows the fractional contribution of residential emissions to annual mean surface  $PM_{2.5}$ , BC, POM, and sulfate concentrations for the baseline simulation. Greatest fractional contributions (15 to > 40 %) to surface  $PM_{2.5}$  are simulated over Eastern Europe (including parts of the Russian Federation), parts of East Africa, South Asia, and East Asia. Over these regions residential emissions contribute annual

mean  $PM_{2.5}$  concentrations of up to  $6 \mu g m^{-3}$ , dominated by changes in POM concentrations of  $2\text{--}5 \mu g m^{-3}$ , with BC and sulfate contributing up to  $1 \mu g m^{-3}$ . Residential emissions contribute up to 60 % of simulated BC and POM over parts of Eastern Europe, Russian Federation, Asia, southeastern Africa, and northwestern Africa. Contribution of residential emissions to surface sulfate concentrations are typically smaller, with contributions of 10–14 % over parts of Asia, Eastern Europe, and the Russian Federation where residential coal emissions are more important (see Sect. 2.2). Over China, residential emissions account for 13 % of simulated annual mean  $PM_{2.5}$ , with larger contributions of 20–30 % in the eastern China. Over India, residential emissions account for 22 % of simulated annual mean  $PM_{2.5}$ , with contributions > 40 % over the Indo-Gangetic Plain. The contributions to  $PM_{2.5}$  are increased to 21 % for China and 34 % for India, when residential carbonaceous emissions are doubled. The contribution of residential emissions to annual mean surface BC (POM) concentrations is  $\sim 40$  % (44 %) for China and  $\sim 60$  % (58 %) for India. When residential carbonaceous emissions are doubled, BC (POM) contributions are increased to 55 % (60 %) for China and 75 % (73 %) for India.

The absolute contribution of residential emissions to PM concentrations are greatest in the NH between 0 and 60° N below 500 hPa (not shown). The fractional contributions within this region are up to 16–24 % for both BC and POM and 1–4 % for sulfate. Residential emissions contribute ~ 20 % of BC and ~ 12–16 % of POM aloft (above 500 hPa) but cause small reductions in sulfate (–1 to –4 %) due to the suppression of nucleation and growth (see Sect. 3.4 for more details).

Table 2 reports the impact of residential emissions on simulated global annual mean BC and POM burden and continental surface PM<sub>2.5</sub> concentrations. In the baseline simulation, the global BC burden is 0.11 Tg with a global mean atmospheric BC lifetime of 4.95 days. This lifetime matches the 4.4 to 5.1 days reported by X. Wang et al. (2014), suggesting that our underestimation of observed BC is not due to fast deposition and short atmospheric lifetime, at least in comparison to other models. In the baseline simulation, residential emissions result in a global BC burden of 0.024 Tg, contributing 22 % of the global BC burden. Residential emissions contribute 12 % of global POM burden. When residential carbonaceous emissions are doubled, residential emissions contribute 33 % of the BC burden and 23 % of the POM burden. Changing from annual mean to monthly varying emissions results in little change to the global BC or POM burden. Emitting carbonaceous particles at very small sizes (*res\_small*) results in a greater fractional contribution to global atmospheric BC (~ 23 %) and POM (~ 18 %) and longer BC lifetime (5.4 days) compared to the baseline simulation. Because the removal of carbonaceous particles in the model is size dependant (particularly for wet deposition), small particles below a critical size can escape removal, leading to enhanced lofting to the free troposphere (FT) where deposition rates are slow. In the *res\_small* simulation, fractional changes in BC burden can be as large as 60–100 % in the FT, compared to 25–40 % in the baseline simulation. Continental surface PM<sub>2.5</sub> concentrations are increased by ~ 2 % in the baseline simulation, which is increased to ~ 3.6 % when carbonaceous residential emissions are doubled.

We further evaluate the simulated contribution of residential emissions to BC concentrations using <sup>14</sup>C source apportionment studies on the island of Hanimaadhoo (Gustafsson et al., 2009; Sheesley et al., 2012; Bosch et al., 2014), which is influenced by pollution transported from the Indian subcontinent. The model simulates well both BC and OC concentrations observed at this location (Sect. 3.1). Figure 8 compares simulated and observed biomass contributions to BC at Hanimaadhoo. The observed contribution depends on not only the time of year the measurements were taken but also the measurement technique used to derive BC (EC). For example, during the same measurement period Gustafsson et al. (2009) found that 46 ± 8 % of EC and 68 ± 6 % of BC originated from non-fossil biomass (January–March). Bosch et al. (2014) estimate that 59 ± 8 % of EC is from non-fossil

**Figure 8.** Comparison of simulated (squares) and observed (circles, error bars show uncertainty range) contributions of non-fossil (residential biofuel and open biomass burning) sources to BC concentrations in Hanimaadhoo, Indian Ocean. Observations are from Gustafsson et al. (2009) (“Gus EC” (thermo-optical) and “Gus BC” (optical) for January–March), Bosch et al. (2014) (“Bos EC” (thermo-optical) for February–March), and Sheesley et al. (2012) (“She EC” (thermo-optical) for November–February). Model simulations are represented by squares: standard emissions (blue: *res\_base*; green: *res\_monthly*) and where residential carbonaceous emissions have been doubled (yellow: *res\_x2*; orange: *res\_monthly\_x2*). Simulated fractional contributions are averaged over the time of year that the observations were made.

biomass (February–March). Sheesley et al. (2012) estimated that 73 ± 6 % of EC originated from non-fossil biomass during the dry season (November–February). The observed contribution of non-fossil BC (EC) therefore spans a range of 46–73 %. Residential biofuel/biomass combustion dominates residential emissions in South Asia (Venkataraman et al., 2005). To estimate non-fossil values from the model, we assume that 90 % of residential BC transported to Hanimaadhoo originates from residential biofuel sources (consistent with ≥ 90 % estimates from the GAINS model), while the remaining non-fossil BC originates from open biomass burning (including agricultural waste and open waste/rubbish burning). We find a small contribution (< 10 % for all simulations) of open biomass burning to simulated BC at Hanimaadhoo, confirming that the non-fossil contribution at this location is likely dominated by residential biomass/biofuel sources, which is supported by the observed consistent con-

**Figure 9.** Simulated annual premature mortality (cardiopulmonary diseases and lung cancer) due to ambient exposure to ambient  $\text{PM}_{2.5}$  from residential emissions (res\_base – res\_off).

tribution from a non-fossil source (Sheesley et al., 2012). The simulated contribution of non-fossil sources to total BC at this location is  $\sim 57$ – $79$  %, depending on the time of year and model simulation. The baseline simulation has a 57 % contribution of non-fossil sources to simulated BC concentrations, with little variation between different times of year due to the annual mean emissions applied in this simulation. Model simulations with monthly varying emissions have a greater contribution of non-fossil sources to BC at this location, as well as greater variability between seasons with a contribution of 62–65 %. Doubling residential emissions increases the contribution of non-fossil sources to  $\sim 72$  % for annual mean emissions and  $\sim 76$ – $79$  % for monthly varying emissions. The spread in observed EC contributions makes it difficult to constrain the contribution of residential emissions, with baseline and doubling of residential BC emissions bracketing the observed range. We do not analyse the non-fossil fraction of OC since OC arises from a larger range of sources including primary emissions and secondary organic aerosol (SOA). Nevertheless, non-fossil water-soluble organic carbon at Hanimaadhoo is dominated ( $\sim 80$  %) by biomass and biogenic sources (Kirillova et al., 2013) but the relative enrichment in the stable ( $\delta^{13}\text{C}$ ) carbon isotope points largely to aged primary biomass emissions sources (Bosch et al., 2014). We estimate the simulated biomass contribution to OC at Hanimaadhoo to be  $\sim 50$ – $70$  % for baseline simulations (res\_base and res\_monthly) and  $\sim 70$ – $80$  % for simulations where residential carbonaceous emissions have been doubled.

### 3.3 Health impacts of residential emissions

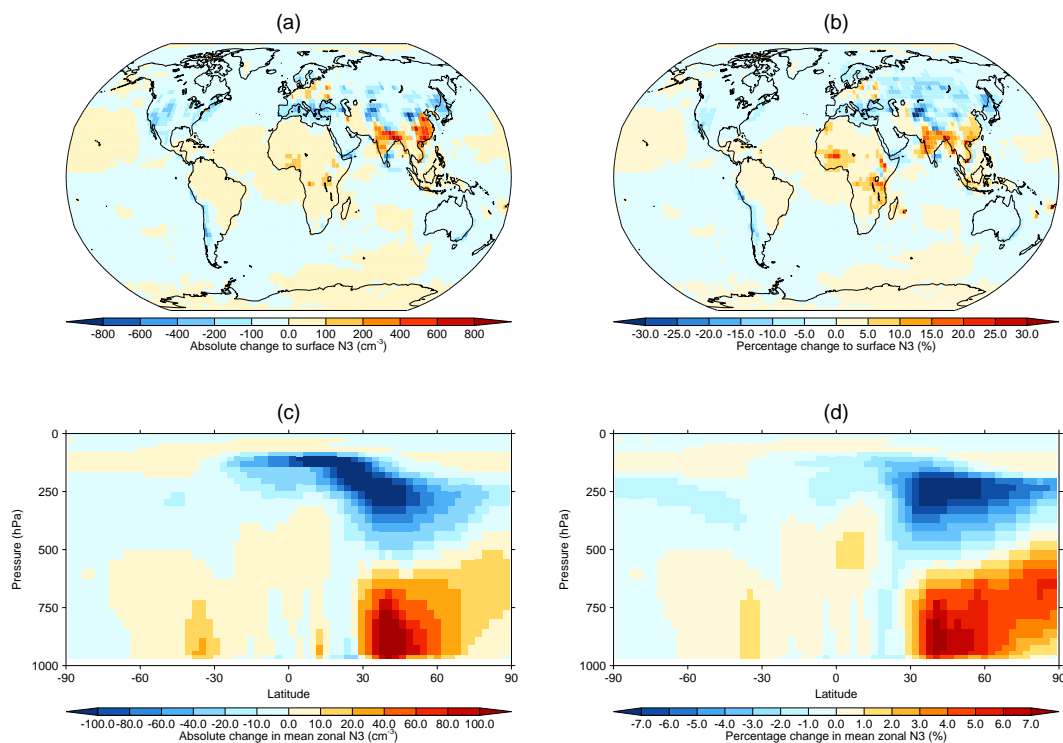

Figure 9 shows the simulated annual excess premature mortality due to exposure to ambient  $\text{PM}_{2.5}$  from residential emissions in the year 2000 for the baseline simulation. Greatest mortality is simulated over regions with substantial res-

**Figure 10.** Simulated global annual premature mortality (cardiopulmonary diseases and lung cancer) for persons over the age of 30 years due to exposure to ambient  $\text{PM}_{2.5}$  from residential emissions. Results are shown for standard emissions (res\_base and res\_monthly) and where residential emissions have been doubled (res\_x2 and res\_monthly\_x2). Mortality is shown for Eastern Europe and the Russian Federation (EEurope), Africa (Africa), South Asia (SAsia), Southeast Asia (SEAsia), East Asia (EAsia), and the rest of the world (as defined by the coloured regions in Fig. 2).

idential emissions and high population densities, notably parts of Eastern Europe, the Russian Federation, South Asia, and East Asia. Table 2 reports total global values for annual mortality due to residential emissions. For the baseline simulation, we estimate a total global annual mortality of 315 000 (132 000–508 000, 5th to 95th percentile uncertainty range). The simulation with monthly varying emissions (res\_monthly) results in total global annual mortality of 308 000 (113 300–497 000), only a 2 % difference from the baseline estimate. Uncertainty in the magnitude of residential emissions causes substantial uncertainty in the simulated impact on human health. When residential carbonaceous emissions are doubled, annual premature mortality increases by 65 % to 519 000 (193 000–830 000) with annual mean emissions and by 68 % to 517 000 (192 000–827 000) with monthly varying emissions. Therefore, uncertainty in the emission budget and uncertainty in the health impacts of PM (as specified by 95 % confidence intervals in the cause-specific coefficients) result in similar uncertainties in estimated global mortality. The CRF function treats all aerosol components as equally harmful, so simulations where residential emissions of POM, BC, and  $\text{SO}_2$  are increased individually show that health effects are most sensitive to uncertainty in POM emissions because this component dominates the total emission mass. Doubling POM emissions (res\_POM $\times 2$ ) increases estimated premature mortality by 50 %, whereas doubling BC emissions (res\_BC $\times 2$ ) results in an 11 % increase and doubling  $\text{SO}_2$  emissions (res\_SO2 $\times 2$ ) leads to a 6.5 % increase.

Figure 10 shows simulated annual total mortality by region. For the baseline simulation, we estimate that resi-

**Figure 11.** Simulated absolute and percentage change in annual mean surface (a–b) and zonal (c–d) number concentration ( $N_3$ ; greater than 3 nm dry diameter) due to residential emissions (res\_base), relative to an equivalent simulation where residential emissions have been removed (res\_base\_off).

dential emissions cause the greatest mortality in East Asia with 121 075 (44 596–195 443, 95 % confidence intervals) annual deaths – 38 % of global mortalities due to residential emissions. We also calculate substantial health effects in other regions, with 72 890 (26 891–117 360) annual deaths in South Asia (28 % of global mortalities) and 69 757 (25 714–112 447) in Eastern Europe and Russia (22 % of global mortalities). Elsewhere we estimate lower mortality with 16 723 (6152–27 018) annual deaths in Southeast Asia (5 %) and 4791 (1751–7784) in sub-Saharan Africa (2 %). Annual premature mortality in sub-Saharan Africa is less than in Asia due to a smaller contribution of residential emissions to  $PM_{2.5}$  concentrations (Fig. 7), combined with typically lower population densities, lower baseline mortality rates for lung cancer and cardiopulmonary disease, and a smaller fraction of the population over 30 years of age.

To our knowledge, this is the first study of the global excess mortality due to ambient  $PM_{2.5}$  from both residential cooking and heating emissions. A recent study by Chafe et al. (2014) concluded that ambient  $PM_{2.5}$  from RSF cooking emissions resulted in 420 000 annual excess deaths in 2005 and 370 000 annual excess deaths in 2010. Chafe et al. (2014) also simulated lower mortality in sub-Saharan Africa (10 800 deaths in 2005) compared to Asia, consistent with our findings. The regions where we estimate the largest health impacts due to residential emissions are dominated by

RSF emissions. In East Asia, residential emissions are dominated by both residential coal and biofuel sources whereas in South Asia emissions are dominated by biofuel sources (Bond et al., 2013).

### 3.4 Impact of residential emissions on total particle number and $N_{50}$ concentrations

Figure 11 shows the change in annual mean surface and zonal mean particle number concentration ( $N_3$ ; particles greater than 3 nm dry diameter) due to residential emissions for the baseline simulation. Residential emissions increase  $N_3$  concentrations over source regions by up to  $800\text{ cm}^{-3}$  due to primary emitted particles. Downwind of source regions,  $N_3$  concentrations are reduced by up to  $\sim 400\text{ cm}^{-3}$ . This reduction is caused by primary particles acting as a coagulation sink for nucleated particles and a condensation sink for nucleating and condensing vapours, suppressing new particle formation (Spracklen et al., 2006), which is broadly consistent with the findings of Kodros et al. (2015) for particle number concentrations due to the effect of biofuel emissions. Residential emissions decrease  $N_3$  concentrations in the FT ( $> 500\text{ hPa}$ ) by up to  $100\text{ cm}^{-3}$  (7 %) due to suppression of nucleation and growth from reduced availability of  $\text{H}_2\text{SO}_4$  vapour due to increased condensation on primary particles.

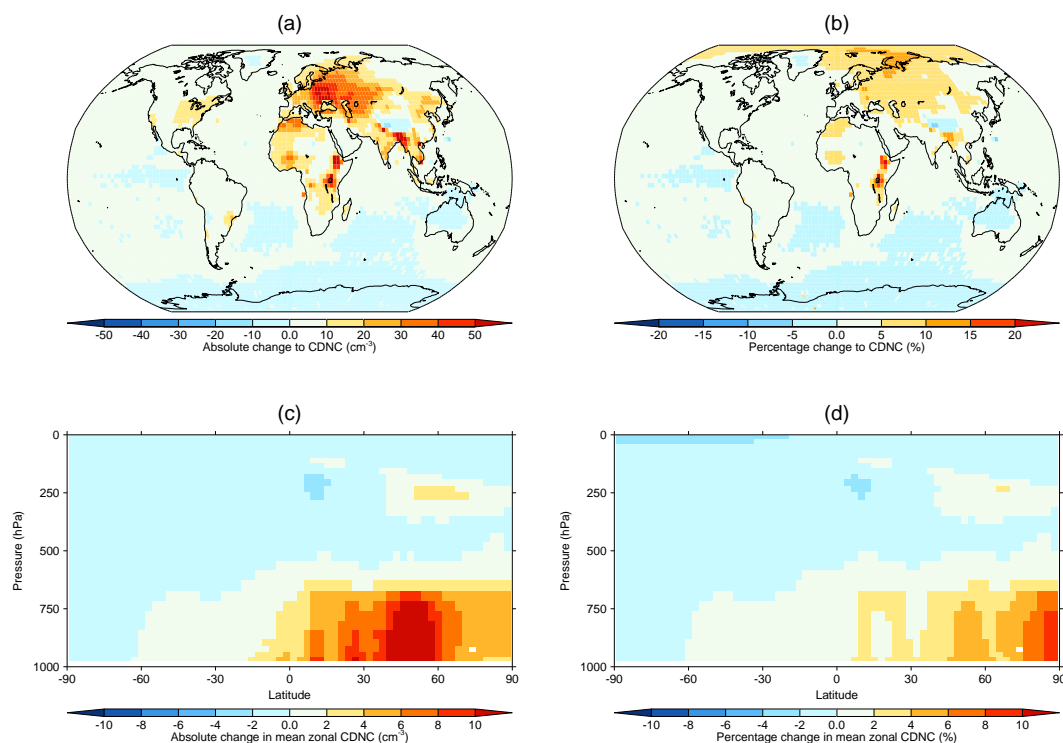

**Figure 12.** Simulated absolute and percentage change in annual mean surface (a–b) and zonal (c–d) soluble  $N_{50}$  concentrations due to residential emissions (res\_base), relative to an equivalent simulation where residential emissions have been removed (res\_base\_off).

In the baseline simulation, residential emissions reduce annual global mean  $N_3$  concentrations by 1.0 % (Table 2). When activation BLN is switched off (res\_BHN), this suppression is no longer important, and residential emissions increase annual global mean  $N_3$  concentrations by 5.7 %. The impact of residential emissions on global particle number depends on the assumed particle size of primary carbonaceous emissions. When residential carbonaceous emissions are emitted at smaller sizes (res\_aero and res\_small), global mean  $N_3$  concentrations are increased by 2.4 and 164 % respectively. This is because a greater number of particles are being emitted per emission mass compared to the baseline simulation.

Figure 12 shows the impact of residential emissions on surface and zonal mean soluble  $N_{50}$  number concentrations for the baseline simulation. Residential emissions increase  $N_{50}$  concentrations over source regions of East Asia, South Asia, and Eastern Europe by up to 300–500  $\text{cm}^{-3}$ . Simulated  $N_{50}$  concentrations are increased by up to 20 % in the Arctic, Eastern Europe, Russian Federation, North Africa, and South Asia. Despite high absolute changes, fractional changes in  $N_{50}$  concentration over East Asia (e.g. China) are smaller (< 15 %) because of higher baseline  $N_{50}$  in this region from other sector emissions (e.g. from industry).  $N_{50}$  concentrations increase globally due to residential emissions, but small reductions (< 5 %) are simulated in the remote Southern Ocean because of the reduction in the amount of

$\text{H}_2\text{SO}_4$  and condensable vapour available for nucleation and growth in FT, which results in reduced entrainment of nucleated particles into the boundary layer. Absolute and fractional changes in zonal mean  $N_{50}$  are greatest between 0 and 60° N and below 500 hPa.

Table 2 reports the global annual mean change in  $N_{50}$  concentrations between different simulations. In the baseline simulation, residential emissions increase global mean surface  $N_{50}$  by  $\sim 5$  %. When primary residential carbonaceous particles are emitted at smaller sizes, residential emissions cause a greater increase in  $N_{50}$  concentrations, with annual global mean  $N_{50}$  concentrations increasing by  $\sim 20$  % in the simulation with smallest particle size (res\_small). Emitting particles at larger sizes results in a smaller increase in global mean  $N_{50}$  (3.1 %) because large particles are more efficiently scavenged. The sensitivity of global mean  $N_{50}$  concentrations to assumptions about emitted particle size is consistent with previous studies (Adams and Seinfeld, 2003; Spracklen et al., 2005b, 2011a). When residential carbonaceous aerosol emissions are doubled, residential emissions increase global annual mean  $N_{50}$  by  $\sim 6.3$  % (res $\times 2$ ). Simulations where individual carbonaceous components are doubled separately (res\_BC $\times 2$  and res\_POM $\times 2$ ) show that  $N_{50}$  is mainly sensitive to change in OC emissions which dominate the carbonaceous aerosol mass. When residential  $\text{SO}_2$  emissions are doubled, residential emissions increase global annual mean  $N_{50}$  by 6.5 %. When activation BLN is assumed not to oc-

**Figure 13.** Simulated absolute and percentage change in annual mean at low cloud height (850–900 hPa) (a–b) and zonal (c–d) CDNC due to residential emissions (res\_base), relative to an equivalent simulation where residential emissions have been removed (res\_base\_off).

cur, residential emissions increase global annual mean  $N_{50}$  by 6.5 % relative to the simulation with no residential emissions. This greater sensitivity is because the baseline  $N_{50}$  concentrations without BLN are lower ( $287.4 \text{ cm}^{-3}$ ) than the baseline simulation ( $364.6 \text{ cm}^{-3}$ ).

### 3.5 Impact of residential emissions on cloud droplet number concentrations

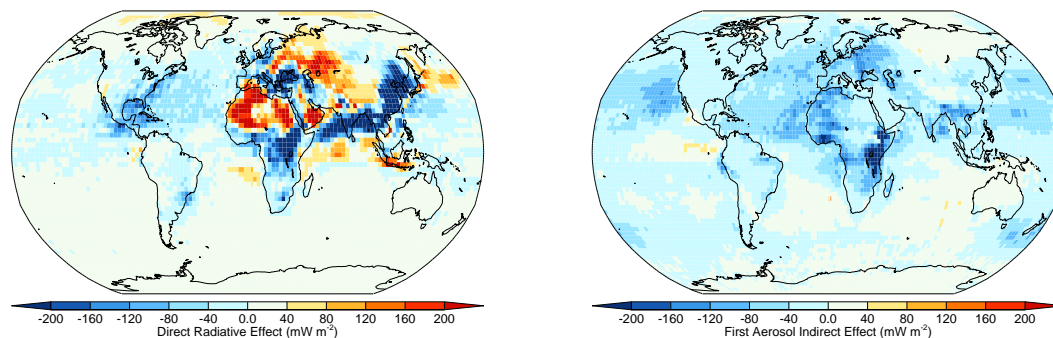

Figure 13 shows the impact of residential emissions on annual mean low-cloud level (850–900 hPa) and zonal mean CDNC for the baseline simulation. Residential emissions increase low-cloud level CDNCs by 20–100  $\text{cm}^{-3}$  over source regions. Smaller absolute and percentage changes in CDNC are simulated over regions with greater baseline CDNCs due to CDNC saturation effects. In contrast, CDNCs increases of 20 % are simulated over regions with low simulated background CDNCs, including parts of East Africa. Simulated absolute increases in zonal mean CDNC are greatest between 0 and 60° N below 500 hPa, whereas greatest fractional changes occur in the Arctic (6–8 %) due to low background concentrations. Small reductions in CDNC are simulated in the FT ( $\sim -2\%$ ) and in the remote Southern Ocean (1–2 %) at cloud level. This is caused by suppressed nucleation in the FT.

In the baseline simulation, residential emissions increase global annual low-cloud level CDNC by 2.1 % (Table 2).

Uncertainty in the emitted particle size of primary carbonaceous emissions causes most of the uncertainty in simulated CDNC. When residential carbonaceous particles are emitted at smaller sizes (res\_small) emissions increase global annual mean CDNC by 20 %. Emitting particles at smaller sizes resulted in greater  $N_{50}$  concentrations, meaning more CCN-sized particles are available to activate. While larger particle sizes can active cloud drops more easily compared to smaller particles, large particles will deplete available water vapour more quickly, which will lower  $SS_{\text{max}}$ , leading to a suppression of small particles being activated. When activation BLN is switched off (res\_BHN), residential emissions cause a greater increase in CDNC (3 %) compared to the baseline simulation, due to lower background CDNCs. Annual mean CDNC are increased by +2.7 % when primary carbonaceous emissions are doubled (res\_×2), but greater increases (+3.3 %) are simulated when residential  $\text{SO}_2$  is doubled separately (res\_SO2×2). This suggests that residential  $\text{SO}_2$  is having a greater effect on CDNC compared to carbonaceous emissions because the small size distribution of secondary sulfate is more efficient in the activation of cloud drops.

### 3.6 Radiative effects of residential emissions

Figure 14 shows annual mean all-sky TOA DRE and first AIE due to residential emissions for the baseline simulation.

**Figure 14.** Annual mean all-sky direct radiative effect (DRE) (left panel) and first aerosol indirect effect (AIE) (right panel) due to residential emissions (res\_base), relative to an equivalent simulation where residential emissions have been removed (res\_base\_off).

**Figure 15.** Global annual mean all-sky direct radiative effect (DRE) (red) and first aerosol indirect effect (AIE) (blue) for all model simulations due to the impact of residential combustion emission, relative to simulations where residential combustion emissions have been removed. DRE and AIE values for each simulation are detailed in Table 2.

Residential emissions result in a negative (cooling) annual mean DRE over large regions of South Asia, East Asia, sub-Saharan Africa, and parts of southern Europe, with values as large as  $-200 \text{ mW m}^{-2}$ . The simulated net negative DRE in South Asia and East Asia is consistent with a previous study (Aunan et al., 2009). In contrast, over parts of Eastern Europe and the Russian Federation, North Africa, the Middle East, and Southeast Asia, residential emissions lead to a positive DRE. Residential emissions cause a negative first AIE over most regions, with values as large as  $-200 \text{ mW m}^{-2}$  over eastern Africa, Eastern Europe, and West Africa. Small positive AIE ( $< 40 \text{ mW m}^{-2}$ ) is simulated in the remote Southern Ocean due to reductions in CDNC as mentioned in Sect. 3.5.

Figure 15 compares the annual mean all-sky DRE and first AIE across the different model simulations (also reported in Table 2). The simulated global annual mean DRE has an uncertain sign, with our estimates between  $-66$  and

$+85 \text{ mW m}^{-2}$ . The baseline simulation results in a global mean DRE of  $-5 \text{ mW m}^{-2}$ , similar to the simulation using monthly varying emissions ( $-8 \text{ mW m}^{-2}$ ). Our estimates differ somewhat to Kodros et al. (2015), who found a homogeneous optical mixing state produced a positive DRE of  $+15 \text{ mW m}^{-2}$  for biofuel emissions; however, because residential emissions differ to biofuel emissions, comparisons become problematic. We therefore assume that differences in radiative effect compared to Kodros et al. (2015) are likely dominated by differences in emissions used and differences in the optical calculation. Doubling residential carbonaceous emissions, but keeping  $\text{SO}_2$  emissions constant, results in a positive global annual mean DRE ( $+21 \text{ mW m}^{-2}$  for res\_ $\times 2$  and  $+10 \text{ mW m}^{-2}$  for res\_monthly\_ $\times 2$ ). This suggests that the carbonaceous (BC and POM) component of residential aerosol in our model exerts a positive DRE, but this is offset by cooling from  $\text{SO}_2$  emissions. Doubling only BC emissions leads to a stronger positive DRE ( $+85 \text{ mW m}^{-2}$ ), whereas negative DRE are simulated for doubling only POM ( $-66 \text{ mW m}^{-2}$ ) or  $\text{SO}_2$  ( $-43 \text{ mW m}^{-2}$ ) emissions. The DRE is also sensitive to emitted particle size, resulting in positive global mean DRE of between  $+1$  and  $+63 \text{ mW m}^{-2}$  when carbonaceous particles are emitted at smaller sizes (res\_aero and res\_small respectively). This change in sign to a positive DRE can be attributed to reduced removal rates for carbonaceous particles emitted at smaller sizes, which leads to larger BC burden, particularly in the FT where BC influence on DRE is most efficient. Residential emissions exert a negative (cooling) but uncertain global annual mean first AIE, estimated at between  $-502$  and  $-16 \text{ mW m}^{-2}$ . The baseline simulation results in a global mean first AIE of  $-25 \text{ mW m}^{-2}$ , similar to the simulation using monthly varying emissions ( $-20 \text{ mW m}^{-2}$ ). Emitting residential carbonaceous aerosol at small sizes contributes most of the uncertainty to simulated first AIE, with estimates between  $-46 \text{ mW m}^{-2}$  (res\_aero) and  $-502 \text{ mW m}^{-2}$  (res\_small) due to a greater increase in global CDNC. We find little sensitivity of the AIE to changes in carbonaceous emission mass: doubling carbonaceous emissions (res\_ $\times 2$ ) changes

AIE by less than  $2 \text{ mW m}^{-2}$  ( $\sim 10\%$ ) due to limited changes in CDNC. In contrast, doubling  $\text{SO}_2$  emissions leads to the greater negative AIE ( $-45 \text{ mW m}^{-2}$ ) due to greater global contribution to CDNCs.

#### 4 Discussion and conclusions

We used a global aerosol microphysics model (GLOMAP) to quantify the impacts of residential emissions on ambient aerosol, human health, and climate in the year 2000. We tested the sensitivity of simulated aerosol to uncertainty in emission amount and seasonal variability, emitted primary carbonaceous aerosol size distributions, and the impact of particle formation.

To evaluate model simulations we synthesised in situ observations of BC, OC, and  $\text{PM}_{2.5}$  concentrations and aerosol number size distribution. The baseline simulation underestimated observed BC, OC, and  $\text{PM}_{2.5}$  concentrations, with the largest underestimation over East Asia and South Asia, consistent with other modelling studies (Fu et al., 2012; Moorthy et al., 2013; Pan et al., 2015). Applying monthly varying emissions (MACCcity emission data set), in place of annual mean emissions (ACCMIP emission), has little improvement on overall model bias but does improve the ability of the model to simulate the observed seasonal variability of aerosol. Doubling residential carbonaceous combustion emissions improved model agreement, but GLOMAP still underestimated BC, OC, and  $\text{PM}_{2.5}$  concentrations. The model typically had a larger underestimation of OC compared to BC concentrations, possibly due to uncertainty in emission factors or potentially due to an underestimation of anthropogenic SOA (Spracklen et al., 2011b).

We used source apportionment studies using  $^{14}\text{C}$  non-fossil BC analysis at the island site of Hanimaadhoo in the Indian Ocean as an additional constraint of the model. Non-fossil sources have been estimated to contribute 46–73% at this location. This large range makes it difficult to constrain the model. With standard emissions (ACCMIP and MACCcity), we estimate a non-fossil fraction of 57–65%, whereas when residential BC emissions are doubled, we simulate a non-fossil fraction of 72–79%.

Overall, our results suggest that residential emissions may be underestimated in the MACCcity and ACCMIP data sets. Uncertainty in aerosol removal processes and transport and missing anthropogenic SOA and nitrate formation may all contribute to underestimation of aerosol mass. Nevertheless, previous modelling studies have also suggested that residential emission data sets underestimate emissions (Park et al., 2005; Koch et al., 2009; Ganguly et al., 2009; Menon et al., 2010; Bergström et al., 2012; Nair et al., 2012; Fu et al., 2012; Moorthy et al., 2013; Bond et al., 2013; Pan et al., 2015). The ACCMIP and MACCcity emission data sets are constructed using national data on fuel use, which implies uniform per capita fuel consumption at the country level. Us-

ing subnational fuel use data, R. Wang et al. (2014) showed that the MACCcity data set underestimated residential emissions over source regions in Asia. Other studies have also had to increase residential emissions over Europe in order to match source apportionment studies (Denier van der Gon et al., 2015). However, Wang et al. (2013) suggested that model bias over China could partly be attributed to coarse model resolution and comparison against urban data and monthly mean observations. Kumar et al. (2015) also showed that a high-resolution model was able to simulate reasonable BC distributions in South Asian region. We have restricted our analysis to rural and background sites but use monthly mean BC and OC data and a relatively coarse-resolution global model. To help resolve uncertainties in residential emission budget, higher-resolution emission inventories (using subnational fuel use data) and higher-resolution model simulations evaluated against long-term and high temporal resolution data are required. In many regions, observational data are lacking; there is an urgent requirement for detailed characterisation of the chemical, physical, and optical properties of aerosol in regions impacted by residential emissions, particularly in the developing world.

Particle number concentrations are generally predicted within a factor of 2 at the limited number of locations where observations are available. Simulated particle number is very sensitive to emitted particle size, which has a large uncertainty. Emitting residential carbonaceous particles at the small end of the range reported by Bond et al. (2006) (geometric mean diameter = 20 nm) substantially overestimates observed particle number, suggesting this assumption is not appropriate for coarse-resolution global models.

Residential emissions contribute substantially to simulated annual mean surface PM concentrations. Greatest fractional contributions (15 to > 40%) to surface  $\text{PM}_{2.5}$  concentrations are simulated over Eastern Europe (including parts of the Russian Federation), parts of East Africa, South Asia, and East Asia. In these regions residential emissions contribute > 50% to total simulated BC and POM concentrations. These findings support previous studies suggesting a large contribution of residential emissions to  $\text{PM}_{2.5}$  concentrations over Asia (Venkataraman et al., 2005; Cao et al., 2006; Klimont et al., 2009; Lei et al., 2011; Cui et al., 2015; Fu et al., 2012; Gustafsson et al., 2009; B. Chen et al., 2013). Our findings suggest that reductions in residential emissions need to be considered alongside mitigation strategies for other PM sources (e.g. industry and transport) within Asia and in even more developed regions such as parts of Europe (Fountoukis et al., 2014).

We estimated the impact of residential emissions on human health due to increased ambient  $\text{PM}_{2.5}$  concentrations and tested the sensitivity to the emission data set and emission budget. We used a log-linear model of relative risk from the epidemiological literature (Ostro, 2004) to relate simulated changes in ambient  $\text{PM}_{2.5}$  concentrations to long-term excess premature mortality for cardiopulmonary dis-

ease and lung cancer for adults (> 30 years of age). In the baseline simulation, we estimate that residential emissions cause 315 000 (132 000–508 000, 5th to 95th percentile uncertainty range) premature mortalities each year. Applying a seasonal cycle to emissions changed our estimate by less than 2 %, with residential emissions resulting in 308 000 (113 300–497 000) premature mortalities each year. Our estimate for residential emissions is equivalent to 8 % of the total mortality attributed to exposure to ambient PM<sub>2.5</sub> from all anthropogenic sources (WHO, 2014b), although we note that methodologies in the two studies are different. Doubling residential carbonaceous emissions, which improved model comparison against observed BC and POM concentrations, increases simulated excess mortality by ~ 64 % to 516 600 (192 000–827 000). Simulated mortality is greatest over regions with large residential emissions and high population densities including East Asia, South Asia, Eastern Europe, and the Russian Federation. We find that half of simulated global excess mortality from residential emissions occurs in China and India alone. Our results are consistent with a previous estimate of RSF cooking emissions on premature mortality (Chafe et al., 2014). The CRFs that are used to estimate long-term premature mortality are uncertain. The log-linear function used here is based on epidemiological studies from North America (Pope III et al., 2002), resulting in greater uncertainty when these functions are extrapolated to other regions (Silva et al., 2013). However, epidemiological studies are not available for all regions, so global mortality estimates often use functions based on these North American studies. Overall, we find that uncertainty in the relationship between PM concentrations and health impacts (as quantified by the 95th percentile range given by the log-linear model) and our measure of uncertainty in emissions (estimated here as a factor of 2 uncertainty) result in comparable uncertainty in the estimated global number of premature mortalities. Future work therefore needs to improve both our understanding of residential emissions and the relationships between enhanced PM concentrations and human health impacts. We also note that the coarse resolution of our global model likely provides a conservative estimate of premature mortality due to residential emissions because it cannot simulate high concentrations associated with highly populated urban and semi-urban areas. Further simulations using higher-resolution models and emission inventories will be required to accurately simulate PM<sub>2.5</sub> concentrations in urban and semi-urban areas. Health effects using more recent CRFs that relate RR of disease to changes in PM<sub>2.5</sub> over a large range of concentration exposures (Burnett et al., 2014) will also be required. In addition, exposure functions, such as the one used in this study, treat all aerosol components as equally toxic, but carbonaceous aerosol, which dominate residential emissions, may be more toxic compared to inorganic or crustal PM (Tuomisto et al., 2008). New exposure response functions will therefore need to account for the different toxicity of chemical components present in atmospheric aerosols.

We used an offline radiative transfer model to estimate the radiative effect (RE) of aerosol from residential emissions. We estimate that residential emissions exert a global annual mean DRE of between  $-66$  and  $+85$  mW m<sup>-2</sup>. The simulated global mean DRE is sensitive to the amount and ratio of BC, POM, and SO<sub>2</sub> in emissions. Doubling residential carbonaceous emissions, but keeping SO<sub>2</sub> emissions constant, results in a positive global annual mean DRE, suggesting that the carbonaceous component of residential aerosol exerts a net positive DRE in our simulations, offset by cooling from SO<sub>2</sub> emissions. We also find a positive DRE when primary carbonaceous emissions are emitted at smaller sizes, but this simulation overestimates observed aerosol number, suggesting it is unrealistic. Discounting this simulation, we provide a best estimate of global mean DRE due to residential combustion of between  $-66$  and  $+21$  mW m<sup>-2</sup> for the year 2000.

Residential emissions exert a simulated global annual mean first AIE of between  $-502$  and  $-16$  mW m<sup>-2</sup>. Uncertainty in emitted primary carbonaceous particle size contributes most of the uncertainty to calculated AIE. Emitting carbonaceous aerosol at smaller sizes results in greater simulated  $N_{50}$  and CDNC and a strong negative AIE as well as in overestimation of observed particle number, suggesting that emission at very small sizes is not realistic. We find little sensitivity to annual mean first AIE due changes in carbonaceous emission mass compared to the baseline simulation. Doubling carbonaceous emissions changes AIE by less than 2 mW m<sup>-2</sup> (~ 10 %), highlighting a non-linear relationship between magnitude of emission and first AIE. Our best estimate of the first AIE due to residential emissions is between  $-52$  and  $-16$  mW m<sup>-2</sup> in the year 2000.

We have restricted our analysis of the RE of residential emissions to the aerosol DRE and first AIE. We treat POM aerosol as scattering, although a fraction of POM aerosol may absorb radiation (Kirchstetter et al., 2004; Chen and Bond, 2010; Arola et al., 2011; X. Wang et al., 2014). Furthermore, our DRE analysis is limited because we do not fully explore the full range of optical mixing states for residential emissions. We assume that BC is mixed homogeneously with scattering species, which provides an upper limit for BC DRE (Jacobson, 2001). A full investigation of the different optical mixing states commonly used in global models, such as in Kodros et al. (2015), would yield a better understanding of DRE from residential emissions. Because we use an offline radiative transfer model, we also do not treat cloud lifetime (second indirect effect) or semi-direct effects (Koch and Del Genio, 2010) and cannot explore additional impacts such as the weakening of the South Asia monsoon, altering of precipitation patterns (Ramanathan et al., 2005), tropical cyclone intensification (Evan et al., 2011), and accelerated melting of glaciers in the Himalayas (Xu et al., 2009).

The introduction of cleaner and fuel efficient residential combustion technologies, processed solid fuels, and clean alternative energy (e.g. natural gas, electricity) has been sug-

gested as one of the fastest ways to reduce residential emissions (UNEP, 2011), thus slowing climate change and improving air quality and human health (WHO, 2009). Our study shows that the complete elimination of residential emissions would result in substantially improved PM air quality and human health across large regions of the world regardless of the uncertainties between the different model simulations explored here.

We have shown that residential combustion emissions exert an uncertain RE, which leads to uncertainties in predicting the climate impact of emission reductions. Our work suggests that residential emission flux, chemical composition, and carbonaceous size distributions need to be better characterised in order to constrain the likely climate impact. Given these uncertainties, the missing processes within our model framework (described above), and the use of an offline radiative transfer model, it is difficult to assess the full climate impacts due to residential emissions. In addition, because we find residential emission amount and resulting RE (particularly aerosol–cloud effects) are not linearly related, our results cannot be used to estimate the impacts associated with smaller, realistic reductions in residential emissions. Future research is needed to explore the air quality and climate impact of realistic emission reductions scenarios that could potentially be achieved through the implementation of cleaner combustion technologies and clean alternative fuels.

More people are using RSF for cooking than at any other point in human history, even though the fraction of the population using these fuels is falling (Bonjour et al., 2013). Over the next few decades (2005–2030), combustion of RSF is projected to increase in South Asia and Africa due to increases in human population (UNEP, 2011). We have reported human health and climate impacts for the year 2000, but in China, residential emissions have increased 34 % during the period 2000–2012 due to the growth of coal consumption (Cui et al., 2015). The use of biomass for heating is also expected to increase in developed countries such as in Western Europe because of rising fossil fuel prices and use of renewable biomass under climate change mitigation policy (Denier van der Gon et al., 2015). The impact of residential emissions on human health and climate is, therefore, likely to persist in the future unless effective mitigation to address the dependence on RSFs is taken.

## Appendix A

Table A1. Acronyms used in this study.

Acronym	Description
ACCMIP	Atmospheric Chemistry and Climate Model Intercomparison Project
AF	Attributable fraction
AIE	Aerosol indirect effect
BC	Black carbon
BHN	Binary homogenous nucleation
BLN	Boundary layer nucleation
CCN	Cloud condensation nuclei
CDNC	Cloud droplet number concentration
CPD	Cardiopulmonary disease
CRF	Concentration response functions
DRE	Direct radiative effect
EC	Elemental carbon
FT	Free troposphere
LC	Lung cancer
LPG	Liquefied petroleum gas
LW	Longwave
MACCity	MACC/CityZEN project
NH	Northern Hemisphere
$N_3$	Number of particles greater than 3 nm dry diameter
$N_{50}$	Number of particles greater than 50 nm dry diameter
$N_{100}$	Number of particles greater than 100 nm dry diameter
NMBF	Normalised mean bias factor
OC	Organic carbon
PM	Particulate matter
PM <sub>2.5</sub>	Particulate matter with an aerodynamic dry diameter of < 2.5 $\mu\text{m}$
POM	Particulate organic matter
RE	Radiative effect
RR	Relative risk
RSF	Residential solid fuel
SOA	Secondary organic aerosol
SW	Shortwave
TOA	Top of atmosphere
