

## RESEARCH LETTER

10.1002/2016GL068825

## Key Points:

- Lightning emissions respond linearly to global mean surface temperature change across a range of climate-chemistry models
- The response of lightning to climate change is strongly dependent on the lightning parameterization used
- Ozone production from lightning NO<sub>x</sub> is 6.5 times more efficient than surface NO<sub>x</sub>, but there is large variation across models

## Supporting Information:

- Supporting Information S1
- Figure S1
- Figure S2
- Figure S3
- Figure S4
- Figure S5

**Abstract** Results from an ensemble of models are used to investigate the response of lightning nitrogen oxide emissions to climate change and the consequent impacts on ozone production. Most models generate lightning using a parameterization based on cloud top height. With this approach and a present-day global emission of 5 TgN, we estimate a linear response with respect to changes in global surface temperature of  $+0.44 \pm 0.05$  TgN K<sup>-1</sup>. However, two models using alternative approaches give  $+0.14$  and  $-0.55$  TgN K<sup>-1</sup> suggesting that the simulated response is highly dependent on lightning parameterization. Lightning NO<sub>x</sub> is found to have an ozone production efficiency of  $6.5 \pm 4.7$  times that of surface NO<sub>x</sub> sources. This wide range of efficiencies across models is partly due to the assumed vertical distribution of the lightning source and partly to the treatment of nonmethane volatile organic compound (NMVOC) chemistry. Careful consideration of the vertical distribution of emissions is needed, given its large influence on ozone production.

### 1. Introduction

Lightning is the dominant source of nitric oxide in the upper troposphere. In this region of the atmosphere, nitrogen oxides (NO<sub>x</sub>) are much more efficient at catalyzing ozone production than surface emissions [Wild, 2007; Wu *et al.*, 2007; Dahlmann *et al.*, 2011]. Lightning, driven by meteorological conditions, is expected to respond to any future changes in climate. Understanding the sensitivity of this response is important for assessment of future ozone concentrations and associated radiative forcing. In addition, the radiative forcing from methane, which is indirectly influenced by NO<sub>x</sub> through reactions with OH, is affected by changes in lightning.

Observational studies suggest that warmer surface temperatures are correlated with increased lightning across diurnal to interannual time scales, although whether such a relationship also applies to longer-term climate change remains uncertain [Williams, 2005]. Estimates from climate-chemistry models suggest that lightning NO<sub>x</sub> emissions will increase by 4–60% per degree increase in global mean surface temperature [Schumann and Huntrieser, 2007], with more recent estimates at the lower end of this range [Zeng *et al.*, 2008; Jiang and Liao, 2013; Banerjee *et al.*, 2014]. There is a gathering consensus on the sensitivity of lightning NO<sub>x</sub> emissions to climate, but this may primarily be due to the similarity of lightning parameterizations used in most models. One isolated study using an alternative lightning parameterization based on ice particle collisions [Jacobson and Streets, 2009] found that lightning NO<sub>x</sub> emissions decreased as temperatures increased.

The approach used in most global scale models applies to a relationship between cloud top height and lightning [Price and Rind, 1992; Price *et al.*, 1997]. This cloud top height relationship provides a reasonable proxy for lightning activity but has several limitations. These include a high sensitivity to any biases in modeled cloud top height and a relatively indirect link to the underlying physical processes [Tost *et al.*, 2007; Wong *et al.*, 2013], which are described by the noninductive charging theory of storms [Reynolds *et al.*, 1957]. Other parameterizations, related to convection [e.g., Meijer *et al.*, 2001; Allen and Pickering, 2002; Grewe *et al.*, 2001; Romps, 2014] or cloud ice [e.g., Deierling *et al.*, 2008; Jacobson and Streets, 2009; Finney *et al.*, 2014; Basarab *et al.*, 2015], have been demonstrated successfully in individual studies but have yet to be widely adopted. To date there has been little investigation into how these alternative approaches respond to climate change.

The recent Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) provides lightning  $\text{NO}_x$  emission ( $\text{LNO}_x$ ) distributions from 12 models using three distinct interactive lightning parameterizations under past, present day, and a range of future emission scenarios [Lamarque *et al.*, 2013]. There are 92 relevant multiyear time slice experiments to compare to a multiyear baseline centered around the year 2000 (Table S1 in the supporting information), allowing a more complete assessment of lightning sensitivity than has been possible in any previous study. The availability of three distinct parameterizations allows us to explore how the choice of parameterization is important for the emission response to climate change. Ten of the models use the same lightning parameterization based on cloud top height [Price and Rind, 1992], and this allows for the most rigorous assessment of the climate response of the cloud top height approach to date. A subset of models, from which ozone production was archived, is then used to explore how these climate-driven changes in lightning  $\text{NO}_x$  emissions can influence global ozone production.

## 2. Statistical Methods

A linear regression assumes independence of data points. However, data produced using the same model share a dependence. To determine robust estimates of the standard errors of regression coefficients when using a multimodel data set such as in this study, it is appropriate to use a linear mixed effect regression.

Linear mixed effect regressions are extensions of linear regression models which include random effects and fixed effects [Pinheiro and Bates, 2000; Bolker *et al.*, 2008]. Fixed effects are either numeric or categorical variables for which interest lies in the specific effects of each category. Random effects are categorical variables for which the effects of each category can be regarded as being sampled from a larger population of possible categories, so that interest lies in variation between categories.

In the context of this study, the inclusion of “model” as a random effect allows for differences in model configuration to be accounted for (through random effects) while estimating the role of explanatory variables (as fixed effects). Both applications of a linear mixed effect regression in this study use a random-slope regression which determines an individual slope and intercept, the random effect, for each model. The random slopes and intercepts are assumed to be correlated.

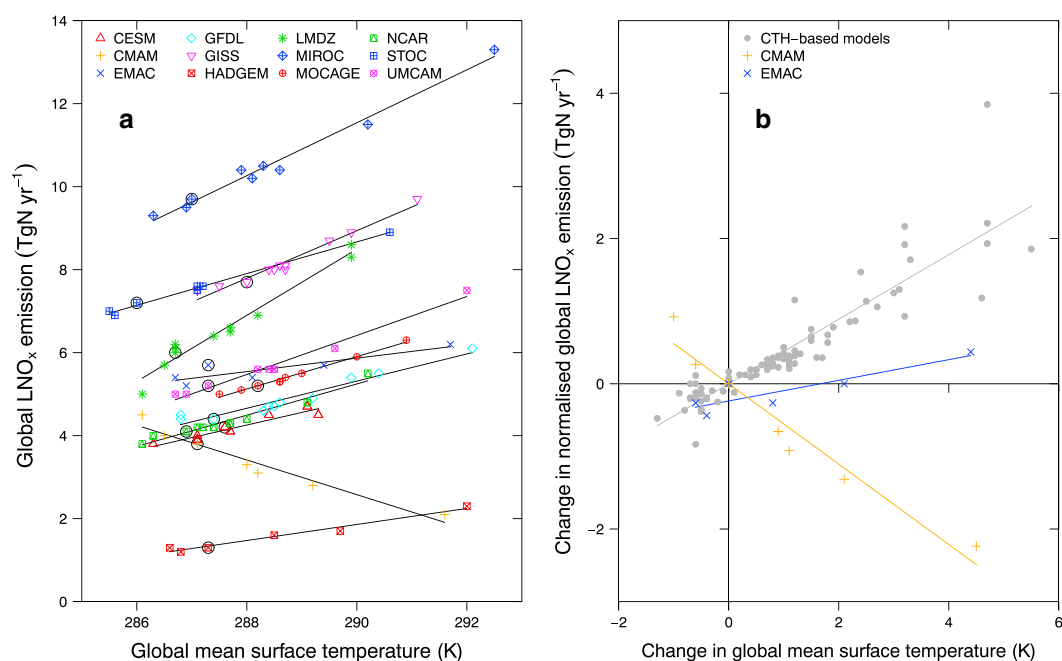

As with a simple linear regression, it is useful to calculate the variance explained by the regression model, the  $R^2$  value. For linear mixed effect models two values of  $R^2$  can be calculated: the *marginal*  $R^2$ , reflecting the proportion of the variance explained by fixed effects, and the *conditional*  $R^2$ , reflecting the variance explained by both fixed and random effects (Text S1 in the supporting information) [Nakagawa and Schielzeth, 2013; Johnson, 2014].

## 3. Response to Temperature

Generation of thunderstorms is only partly related to the surface temperature and reflects local rather than global conditions. However, based on past studies, surface temperature provides a simple proxy for changes in the atmosphere that affect lightning.

Figure 1a shows the relationship between total annual lightning  $\text{NO}_x$  emissions and global mean surface temperature. Each data point is from a single time slice experiment, averaged over multiple years as specified in Table 2 of Lamarque *et al.* [2013], where each year has identical anthropogenic and biomass burning emissions. The data used encompass time slices of the present-day baseline, historical 1850 and 1980 simulations, and all future scenarios using the Representative Concentration Pathways (RCPs) produced by each model. A significant linear relationship between  $\text{LNO}_x$  and surface temperature is evident for each model. This is the first time enough comparable data have been produced from a range of models to allow robust conclusions regarding the form of the relationship.

Despite the clear conclusion that each model exhibits a linear relationship, Figure 1a shows a substantial spread between the models. Sources of intermodel spread include the magnitude of the baseline emissions, which vary from 1.3 to 9.7  $\text{TgN yr}^{-1}$  and differences in the baseline mean surface temperature which ranges from 286.0 to 288.2 K (see circled points in Figure 1a). We remove these variations by normalizing the baseline lightning  $\text{NO}_x$  emissions in each model to 5  $\text{TgN}$  and consider changes in temperature and lightning  $\text{NO}_x$  emissions relative to this baseline (Figure 1b). The choice of 5  $\text{TgN}$  is based on the best estimate for present-day emissions [Schumann and Huntrieser, 2007].

**Figure 1.** Total annual lightning  $\text{NO}_x$  emissions against global mean surface temperature for the ACCMIP models with interactive lightning schemes. (a) Absolute global emissions and surface temperatures; (b) changes in lightning  $\text{NO}_x$  emissions with respect to the year 2000 baseline, normalized to 5 TgN in year 2000, and grouped according to lightning parameterization. Circled points in Figure 1a are from the year 2000 baseline simulations.

Results from models using the cloud top height (CTH) approach are grouped together. These models show a consistent linear response of  $\text{LNO}_x$  to temperature once the differences in present-day surface temperature and global emission totals are adjusted for. A linear mixed effect regression on the data points simulated by models using the cloud top height approach has been applied. Surface temperature is the regressed fixed effect, while random effects are a random intercept for each model and a random slope for the interaction between each model and the effect of surface temperature. All effects considered are significant at the 5% level, and the regression model has a marginal  $R^2$  of 0.82 and a conditional  $R^2$  of 0.96.

A robust estimate of the lightning  $\text{NO}_x$  emission climate response of  $0.44 \pm 0.05 \text{ TgN K}^{-1}$  is found for models using the cloud top height approach (individual model fits are provided in Table S2). This corresponds to  $8.8 \pm 1.0\%(\text{baseline}) \text{ K}^{-1}$ , where the uncertainty range represents 1 standard error. This is lower than the median determined by Schumann and Huntrieser [2007] but similar to recent estimates which have a range of 5.5–16%  $\text{K}^{-1}$  (Text S2 in the supporting information) [Zeng *et al.*, 2008; Jiang and Liao, 2013; Banerjee *et al.*, 2014]. Differences in the  $\text{LNO}_x$  response among models using the cloud top height approach arise from differing responses to climate change from convective and microphysical schemes, the vertical resolution for resolving cloud top height, and structural differences in implementation of the approach. Details of the lightning parameterization used by each model are described in Text S3 and Table S3.

The ACCMIP data allow for a robust estimate of the sensitivity of the cloud top height approach. However, the two ACCMIP models using alternative parameterizations provide rather different estimates. The EMAC model uses a combination of updraft mass flux within the cloud and cloud depth [Grewe *et al.*, 2001] and shows a much weaker sensitivity ( $0.14 \text{ TgN K}^{-1}$ ) than the cloud top approach. The CMAM model uses a parameterization based on updraft mass flux at 440 hPa [Allen and Pickering, 2002] and shows the opposite response of a reduction in  $\text{LNO}_x$  with increasing temperature ( $-0.55 \text{ Tg K}^{-1}$ ).

The various responses described above for each parameterization fundamentally depend on the changes in convection simulated by the models. It is possible that these two models are anomalous in their responses to climate change for convection. Further investigation of convection in the different models or application of different parameterizations would be needed to establish this. However, it is unlikely that the models with different lightning parameterizations also have anomalous convection responses and therefore we suggest that the lightning parameterizations are the source of the different responses seen. It is also possible that

changes in cloud top height differ somewhat from changes in the intensity of convective updrafts. *Stevenson et al.* [2005] and *Banerjee et al.* [2014] have found that in some locations the occurrence of deep convection decreases under climate change but that the depth increases. Our findings suggest that it is vital to determine whether the cloud top height approach provides the most appropriate representation of lightning or whether a greater diversity of lightning parameterizations is needed. Uncertainty remains as to whether lightning  $\text{NO}_x$  emissions will increase or decrease in the future.

#### 4. Spatial Variation of Response to Temperature

The impacts of  $\text{LNO}_x$  on atmospheric chemistry and radiative forcing are dependent on the spatial distribution of emissions as well as the global total [*Liaskos et al.*, 2015; *Finney et al.*, 2016]. We consider here the spatial distribution of  $\text{LNO}_x$  and change in  $\text{LNO}_x$  between present day and future, and whether there is anomalous behavior underlying the distributions.

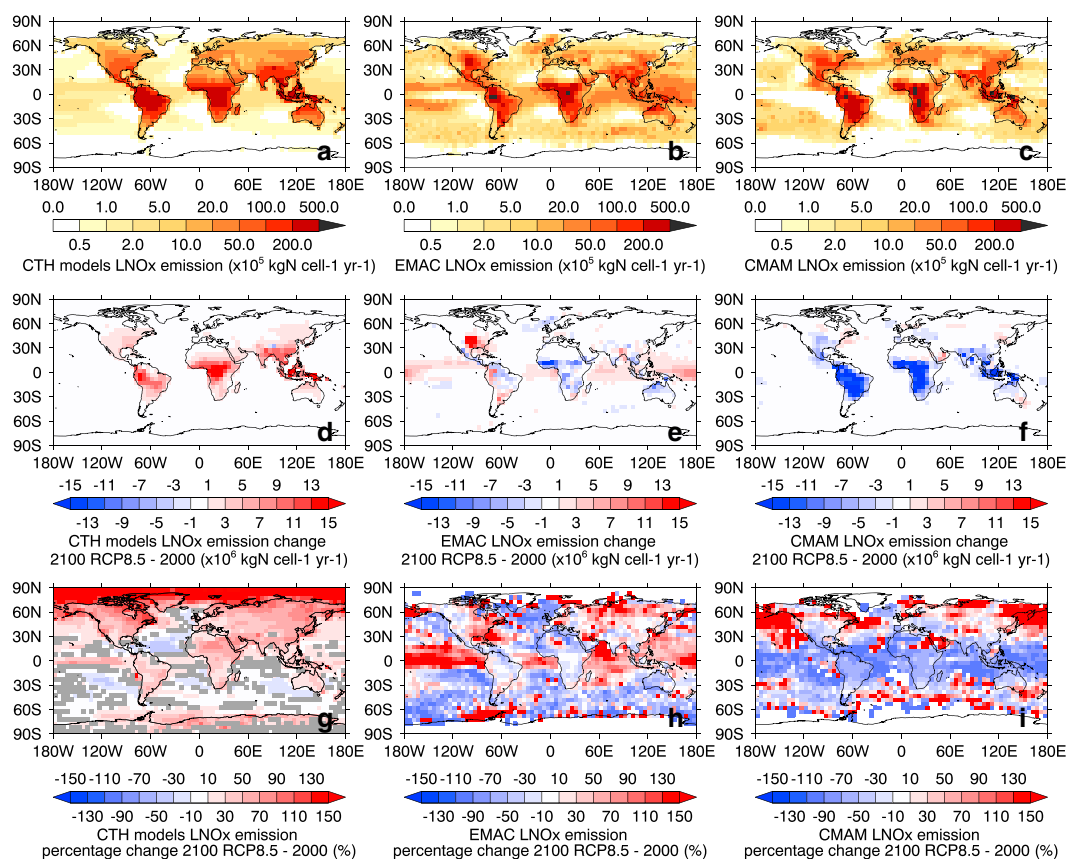

Figures 2a–2c shows the mean baseline (year 2000) distribution of lightning  $\text{NO}_x$  emissions from eight models using the cloud top height approach for which spatial distributions of emissions are available, as well as from each of the models using alternative schemes. The emission distributions of all three approaches represent, to a reasonable extent, the climatological distribution of lightning flash rate provided by the Lightning Imaging Sensor and Optical Transient Detector [*Cecil et al.*, 2014]. In particular, they show lightning  $\text{NO}_x$  emission peaks in tropical continental locations and lower values toward the poles and over the oceans. The distributions of change in surface temperature (Figure S4) and precipitation (Figure S5) between the present day and year 2100 using the RCP8.5 scenario are shown in the supporting information. CMAM and EMAC do not simulate anomalous temperature or precipitation changes compared to the other ACCMIP models. The robustness of these two models, which use alternative lightning parameterizations, among the other ACCMIP models regarding these three variables gives confidence that they are not outliers in terms of their broad representation of climate change.

Figures 2d–2f show the absolute changes in lightning  $\text{NO}_x$  emissions between the present day and year 2100 using the RCP8.5 scenario for each type of lightning parameterization. As with the global total  $\text{LNO}_x$  changes in Figure 1, the three approaches represent largely positive (Figure 2d), mixed (Figure 2e), and largely negative changes (Figure 2f). From all three approaches, it is clear that changes in  $\text{LNO}_x$  under future climate change are nonuniform. The largest absolute changes typically occur where there are highest baseline lightning  $\text{NO}_x$  emissions and the sign of these changes are generally consistent with the sign of global total  $\text{LNO}_x$  changes found with each lightning parameterization.

The percentage changes in lightning  $\text{NO}_x$  emissions between the present day and year 2100 using the RCP8.5 scenario are shown in Figures 2g–2i. The changes in the models using alternative schemes appear more noisy. This is partly due to averaging over a number of models that use CTH (Figure 2g), but even compared to individual model simulations of  $\text{LNO}_x$  based on cloud top height the alternative schemes produce a more heterogeneous response (Figure S3). The cloud top height will be partly limited by the tropopause which will vary smoothly and, therefore, may lead to smoothness in the simulated  $\text{LNO}_x$  distribution by models using the CTH approach.

Percentage changes between present day and future are generally large over ocean as well as over land. Most of the globe experiences changes of  $>10\%$ . While absolute changes in  $\text{LNO}_x$  are small away from dominant source regions, the percentage changes are larger away from high-emission regions. Such large relative changes may be important in remote locations where there are few other sources of  $\text{NO}_x$ .

There is agreement between the different schemes on the sign of the change in some locations which can be seen in Figures 2g–2i. Mostly, these are located in the midlatitudes. Increases in  $\text{LNO}_x$  in the Northwest Atlantic and Pacific suggest an increase in lightning activity within northern midlatitude storms or a shift in location of the storm tracks. Decreases in the Southeast Pacific are consistent with significant drying reported in the IPCC AR5 report by *Collins et al.* [2013, Figure 12.22]. *Collins et al.* [2013] indicated significantly increased rainfall in Russia and eastern Canada in the year 2100 under RCP8.5, corresponding to increases in  $\text{LNO}_x$  in Figures 2g–2i, thereby suggesting that the changes in rainfall in these regions correspond to changes in the frequency or intensity of thunderstorms. There are many other locations where changes in lightning  $\text{NO}_x$  emissions do

**Figure 2.** Annual vertically integrated lightning  $\text{NO}_x$  emission distribution for the year 2000 baseline, and absolute and percentage change with respect to RCP8.5 year 2100. Annual emissions for year 2000 distributions are normalized to 5 TgN for all models with the same normalization factors applied to year 2100 RCP8.5 emissions. Shown are (a–c) the baseline distributions for year 2000, (d–f) the absolute changes in distribution for the year 2100 RCP8.5 experiments, and (g–i) the equivalent percentage changes. The left column plots are the mean of eight models using the cloud top height approach. The middle and right column plots are the individual results for the EMAC and CMAM models, respectively. Mean values are calculated after scaling and regridding all models to a common resolution ( $5^\circ \times 5^\circ$ ). In Figure 2g the greyed cells represent grid cells in which there is not at least five models that estimate the same sign of change.

not correspond to similar changes in precipitation. The nonuniformity of these changes in lightning is an important argument for using interactive lightning schemes that are not constrained spatially by present-day observations.

### 5. Ozone Production

Ozone is sensitive to a large number of variables influenced by climate change and so it is difficult to attribute changes in ozone concentration directly to changes in lightning  $\text{NO}_x$  emissions. Changes in temperature, humidity, deposition, other ozone precursor emissions, and stratosphere-troposphere exchange all contribute to changes in ozone [Fiore et al., 2012; Doherty et al., 2013; Young et al., 2013]. The most direct impact of lightning  $\text{NO}_x$  emissions on ozone is through chemical production. Based on model sensitivity studies, Wild [2007] found that an increase in  $\text{LNO}_x$  produced  $\sim 3$  times more global tropospheric ozone production per Tg(N) than an increase in surface  $\text{NO}_x$  emissions. Using alternative methods, Wu et al. [2007] and Dahlmann et al. [2011] found that  $\text{LNO}_x$  produced 6 and 5 times more ozone than surface  $\text{NO}_x$ , respectively. This disproportionately large effect is due to lightning  $\text{NO}_x$  emission in the middle and upper troposphere where temperatures are cooler,  $\text{NO}_x$  and ozone have longer lifetimes, and where ozone production efficiency is high.

Tropospheric ozone chemical production fluxes were archived from a subset of six models during ACCMIP. Relevant emission variables from all time slices and scenarios (Table S1) are used here to perform a linear mixed effect regression to describe global tropospheric ozone production. Fixed effects for lightning  $\text{NO}_x$ ,

surface  $\text{NO}_x$ , CO and NMVOC emissions, and the methane tropospheric burden were included within the initial mixed effect regression, along with random effects for “model” and for the interaction between model and the effect of lightning. The surface  $\text{NO}_x$  variable includes  $\text{NO}_x$  emissions from aircraft, but these are less than 2% of the total emissions and we assume that their effects are small.

A stepwise selection process, based on the Akaike information criteria (AIC) [Burnham and Anderson, 2002], was used to identify whether the initial regression model could be simplified, and this led to NMVOC emissions and CO emissions being removed. The remaining explanatory variables all have significant coefficients with  $p < 0.05$ . The model has a *marginal*  $R^2$  of 0.57 and a *conditional*  $R^2$  of 0.99. An equation for the fitted linear model is given by

$$\hat{P} = 104(\pm 37)E_{\text{LNO}_x} + 16.0(\pm 0.9)E_{\text{surfNO}_x} + 0.0793(\pm 0.0104)B_{\text{CH}_4} - 1.85(\pm 14.74) + U_{1,m}E_{\text{LNO}_x} + U_{2,m} \quad (1)$$

where  $\hat{P}$  is the estimated global tropospheric ozone production ( $\text{mol}(\text{O}_3) \text{ yr}^{-1}$ ),  $E_{\text{LNO}_x}$  and  $E_{\text{surfNO}_x}$  are emissions of lightning  $\text{NO}_x$  and surface  $\text{NO}_x$  ( $\text{mol}(\text{N}) \text{ yr}^{-1}$ ), and  $B_{\text{CH}_4}$  is methane tropospheric burden ( $\text{mol}(\text{CH}_4)$ ). Ranges given in equation (1) are the standard errors associated with each coefficient. The random model slope,  $U_{1,m}$ , represents an adjustment to the fixed lightning effect, and the random model intercept,  $U_{2,m}$ , an adjustment to the regressed intercept, for each model,  $m$ . There are six models and therefore  $U_1$  and  $U_2$  are each a vector of six values. The mean of the values of any random effect,  $U$ , is zero. The standard deviations of the values of  $U_{1,m}$  and  $U_{2,m}$  are 75 and 28, respectively.

The coefficients of equation (1) represent the number of moles of ozone produced for each mole of the species, i.e., the ozone production efficiency (OPE). For example, the OPE associated with surface  $\text{NO}_x$  sources is  $16 \text{ mol}(\text{O}_3) \text{ mol}^{-1}(\text{N})$ . The underlying fixed  $\text{LNO}_x$  effect found in the regression is 6.5 times larger than that of surface  $\text{NO}_x$  sources, similar to that found by Wu *et al.* [2007] and Dahlmann *et al.* [2011], and representing a disproportionately larger efficiency of  $\text{LNO}_x$  in producing ozone.

It is important to consider the size of the emissions or burden in combination with regression coefficients to fully understand the context of the statistical regression results. By applying the regressed ozone production efficiencies of equation (1) for  $E_{\text{LNO}_x}$  including the random slopes,  $E_{\text{surfNO}_x}$  and  $B_{\text{CH}_4}$ , to the emissions in each time slice experiment, we can attribute a proportion of the estimated ozone production to each of the individual effects. There are 50 time slice experiments used (summarized in Table S1). The mean and range for the three effects are as follows:  $E_{\text{LNO}_x}$  41% (3–78%),  $E_{\text{surfNO}_x}$  38% (12–68%), and  $B_{\text{CH}_4}$  21% (9–51%). These results show that the three effects, at least for the range of experiments in ACCMIP, produce similar amounts of ozone, with  $\text{CH}_4$  generally producing less ozone and with a wider range of contributions to ozone production from  $\text{LNO}_x$  across the experiments.

## 6. Causes of Variability in Ozone Production Efficiency

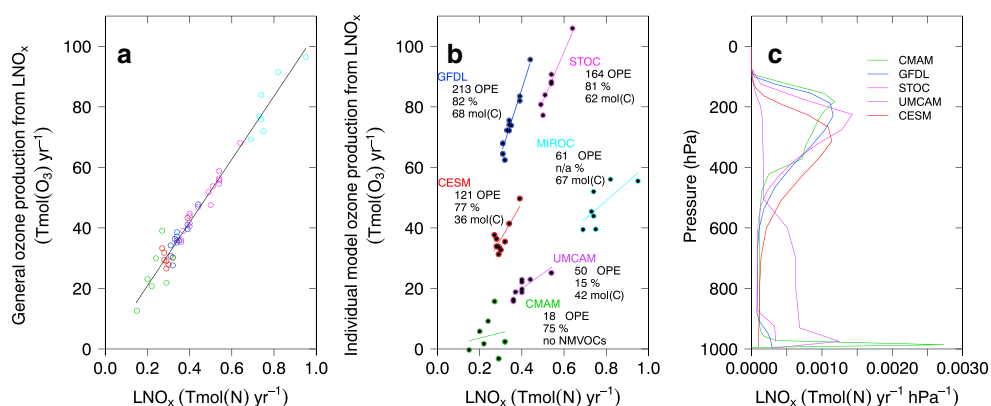

The regression model described by equation (1) provides a means to remove the estimated ozone production by species other than  $\text{LNO}_x$  and therefore study the production by  $\text{LNO}_x$  alone. In addition, the random slope values,  $U_{1,m}$ , determined in the regression can either be removed to see the estimated underlying ozone production from  $\text{LNO}_x$  across models or included to see the estimated ozone production from  $\text{LNO}_x$  in each model. These components of ozone production are shown by the partial residuals of ozone production against  $\text{LNO}_x$  in Figures 3a and 3b.

The partial residual is the actual ozone production with the estimated ozone production of some terms in the regression removed. Figure 3a is the conditional partial residual of ozone production with respect to lightning  $\text{NO}_x$  emissions,  $\epsilon_1$ , i.e., the general relationship across models given by the fixed effect of  $E_{\text{LNO}_x}$  in equation (1) and described by equation (2):

$$\epsilon_1 = \hat{P} - 16.0E_{\text{surfNO}_x} - 0.0793B_{\text{CH}_4} - 1.85 - U_{1,m}E_{\text{LNO}_x} - U_{2,m} \quad (2)$$

Figure 3b shows the individual model relationships between ozone production and  $\text{LNO}_x$ ,  $\epsilon_2$ , i.e., the combination of the fixed effect,  $E_{\text{LNO}_x}$  and individual random slopes,  $U_{1,m}$ . This partial residual is described by equation (3):

$$\epsilon_2 = \hat{P} - 16.0E_{\text{surfNO}_x} - 0.0793B_{\text{CH}_4} - 1.85 - U_{2,m} \quad (3)$$

**Figure 3.** Tropospheric ozone production from lightning NO<sub>x</sub> emissions and the role of NMVOC emissions and the vertical distribution of lightning NO<sub>x</sub> emissions. (a) “General ozone production from LNO<sub>x</sub>” is a partial residual with respect to LNO<sub>x</sub> described by equation (2). (b) “Individual model ozone production from LNO<sub>x</sub>” is a partial residual with respect to LNO<sub>x</sub> described by equation (3). The text in Figure 3b for each model is, from top to bottom, the ozone production efficiency (OPE) from LNO<sub>x</sub>, the percentage of baseline lightning NO<sub>x</sub> emissions in the middle and upper troposphere [500–100 hPa], and the mean NMVOC emissions. (c) The baseline global LNO<sub>x</sub> vertical distribution. The MIROC model is not included in Figure 3c because the emission distribution was not archived. For Figure 3c, values of pressure are based on a uniform 1000 hPa surface pressure, and annual lightning NO<sub>x</sub> emissions are normalized to 5 TgN.

These partial residuals demonstrate the effect of lightning NO<sub>x</sub> emissions and clearly reveal the differences in OPE between the models.

The vertical distribution of LNO<sub>x</sub> differs greatly between the models, as shown in Figure 3c. Vertical distribution methods are based upon modeled updrafts, prescribed distributions [Pickering *et al.*, 1998; Ott *et al.*, 2010], or air density [Goldenbaum and Dickerson, 1993; Stockwell *et al.*, 1999; Jourdain and Hauglustaine, 2001]. The LNO<sub>x</sub> vertical distribution method used by each model in ACCMIP is given in Table S3.

The proportion of lightning NO<sub>x</sub> emission in the middle and upper troposphere (500–100 hPa) and the gradient (OPE) for each individual model determined by the mixed effect regression are presented in Figure 3b. Although there are relatively few models, there is a direct relationship between the amount of ozone in the middle and upper troposphere and the OPE of lightning. An exception is the CMAM model which has a relatively weak relationship between ozone production and LNO<sub>x</sub> and a low OPE. It would require a targeted study to identify the cause of this difference, but we note that CMAM does not include NMVOC chemistry, representing this instead through extra CO emissions. The majority of NMVOC emissions are in the form of biogenic emissions and are high over tropical rainforests where lightning activity is also high. It is possible that the combined emissions of NMVOC and LNO<sub>x</sub> increase OPE in these regions through a greater radical pool. CMAM also has a different spatial distribution of the response of LNO<sub>x</sub> to climate change compared to other models. Changes in regions of lower ozone production may contribute to a weaker relationship between ozone production and LNO<sub>x</sub>.

The considerations above encourage further research to understand variability among models. LNO<sub>x</sub> and OPE will have seasonal and regional responses to climate change which have not been investigated here. Furthermore, research into the effect on OPE of LNO<sub>x</sub> being concentrated within convective outflow plumes would be valuable, given that this feature is not captured by the resolutions of ACCMIP models. Dedicated sensitivity simulations within a climate-chemistry model would allow quantification of the role of the vertical emission distribution of lightning NO<sub>x</sub> and the representation of NMVOCs on the OPE of LNO<sub>x</sub>. This would permit these effects to be isolated and allow determination of the contribution of LNO<sub>x</sub> differences to the intermodel variation of OPE in Figure 3b. The standard deviation of individual model estimates of OPE can be used as a proxy for the uncertainty on the fixed LNO<sub>x</sub> effect discussed in section 5, suggesting that the OPE of LNO<sub>x</sub> is  $6.5 \pm 4.7$  times that of surface NO<sub>x</sub> sources.

## 7. Conclusions

The large data set of model results archived for ACCMIP has allowed a rigorous analysis of the climate sensitivity of lightning NO<sub>x</sub> emissions for models using the cloud top height parameterization of *Price and Rind* [1992]. This parameterization is widely used and performs very similarly across models with a positive linear response of  $0.44 \pm 0.05$  TgN K<sup>-1</sup> for a baseline annual emission of 5 TgN. Two models using different parameterizations of lightning simulate a weaker and an opposite climate response of lightning NO<sub>x</sub> emissions. Therefore, despite the important role that lightning NO<sub>x</sub> emission plays in ozone chemistry, it is clear from the two ACCMIP models using alternative lightning schemes that there cannot be complete confidence in the magnitude or even sign of the lightning NO<sub>x</sub> emission sensitivity to climate change. While there is agreement among the three parameterizations in a few locations regarding the projected spatial change of LNO<sub>x</sub> in future, generally this is as uncertain as the global changes.

There is no indication that the models using alternative schemes are outliers in terms of their representation of surface temperature or precipitation change. We therefore conclude that the different responses of lightning to climate change are due to the use of different lightning parameterizations. Studies establishing the climate sensitivity of multiple lightning parameterizations within the same model are needed to confirm whether the results here solely reflect the different parameterizations. The cloud top height approach has been well characterized in this study thereby providing a useful reference point in understanding the behavior of alternative schemes. We therefore suggest that climate-chemistry modeling groups consider additional simulations with alternative lightning schemes, as a greater diversity of schemes would help advance our understanding of uncertainties in the response of lightning NO<sub>x</sub> to climate change and its subsequent effects on ozone.

Uncertainty in the climate response of lightning will undoubtedly lead to uncertainty in the changes in ozone production from LNO<sub>x</sub>. The tropospheric ozone production from LNO<sub>x</sub> and other sources has been quantified using the data from a selection of models in ACCMIP. The results suggest that lightning NO<sub>x</sub> emissions are  $6.5 \pm 4.7$  times more efficient than surface NO<sub>x</sub> sources at producing ozone in the troposphere. The method for distributing emissions vertically as well as the treatment of emissions of NMVOCs appear to be responsible for at least some of this variability in ozone production efficiency from lightning. Therefore, direct determination of the role of the vertical LNO<sub>x</sub> distribution for ozone production is necessary before a consistent approach among models can be developed.

## Acknowledgments

Declan Finney was supported by a Natural Environment Research Council grant NE/K500835/1. Adam Butler's contribution was supported by the Rural and Environment Science and Analytical Services (RESAS) Division of the Scottish Government. We thank model groups contributing to ACCMIP for use of their data, in particular, David Plummer for discussions regarding CMAM. Access to the ACCMIP data set can be requested from the British Atmospheric Data Centre. We are grateful to Oliver Binks and Claudia Steadman for discussions regarding mixed effects models.
