**The frictional resistance induced by bacterial based biofouling within drainage pipelines**

Journal:	<i>Journal of Hydraulic Research</i>
Manuscript ID	TJHR-2015-0061.R3
Manuscript Type:	Research paper
Date Submitted by the Author:	27-Apr-2016
Complete List of Authors:	Cowle, M; Mott MacDonald; Hydro-environmental Research Centre, Cardiff University, Cardiff School of Engineering Babatunde, A; Hydro-environmental Research Centre, Cardiff University, Cardiff School of Engineering Bockelmann-Evans, B; Hydro-environmental Research Centre, Cardiff University, Cardiff School of Engineering
Keywords:	biofilm, bacterial based biofouling, drainage pipelines, equivalent roughness, non-universal von Kármán constant, pipe flow
JHR Keywords:	Biofilms < Eco-hydraulics, Boundary layer turbulence < Turbulent flows, Sewer hydraulics < Applied fluid mechanics and hydraulic engineering, Pressure and temperature measurements < Instrumentation, measurements and experimental methods, Laboratory studies < Instrumentation, measurements and experimental methods

# The frictional resistance induced by bacterial based biofouling in drainage pipelines

## ABSTRACT

This paper aims at improving the current understanding of bacterial-based biofouling in drainage pipelines. Using a purpose built pipeline facility consisting of a high density polyethylene pipe, biofilms were incubated with synthetic wastewater for 20 days at three steady-state flow regimes. The results obtained have shown that the presence of a biofilm can cause a significant increase in frictional resistance. The magnitude of a biofilm's frictional resistance is a function of the shear conditions under which the biofilm is incubated. In particular, the lower the conditioning shear, the higher the frictional resistance imparted by the biofilm. This is attributed to the thickness and roughness distribution induced by such conditions, and it serves to highlight the problem of characterising a biofilm's effective roughness using a single roughness scale. The study has also supported the earlier finding that the von Kármán constant is non-universal, and is dependent on Reynolds number for biofouled pipes.

*Keywords:* Biofilm; bacterial based biofouling; drainage pipelines; equivalent roughness; flows in pipes; von Kármán constant

## 1 Introduction

It is widely acknowledged that population growth, urbanisation and climate change will put significant pressure on pipeline infrastructure over the next century. In particular, the magnitude and intensity of precipitation in extreme events is predicted to increase as a direct result of climate change. The increased runoff and storm water discharge expected has the potential to increase the frequency and magnitude of surcharge and flooding, particularly in highly populated urban areas. Global population growth is likely to further exacerbate the impacts of climate change on sewer systems, especially in urbanised areas where it is predicted that the majority of the growth will be absorbed. The effective management of Drainage Networks (DNs) is therefore of paramount importance to the water industry; and it represents one of the industry's greatest challenges from both an operational and public health standpoint. This challenge is exacerbated by the environmental complexities of DN, which are characterised by highly diverse and variable flow rates, temperatures and their contents. Fouling mechanisms such as bacterial based biofouling, contribute to, and are governed by these inherent complexities. Bacterial based biofouling refers to the natural, albeit sometimes undesirable process through which a complex microbiological slime layer – known as a biofilm – forms upon a surface. Biofilms in pipelines are generally classified on the macro-scale as either low-form gelatinous or filamentous. Their presence can cause a significant

1  
2  
3 increase in boundary shear stresses and surface roughness (Barton, 2006; Barton Sargison,  
4 Buia, Walker, 2008).

5  
6 The magnitude of the change in surface roughness caused by biofouling is a function  
7 of the physical nature of a biofilm (Barton, 2006). Biofilms are viscoelastic in nature and  
8 through a vibrating and oscillating action, they have the ability to remove significant amount  
9 of energy from a flow field (Andrewartha, 2010; Walker, Sargison, & Henderson, 2013). As a  
10 result, a biofilm's effective roughness can be significantly higher than that predicted based  
11 upon traditional wall similarity hypothesis, i.e. using the classical Nikuradse-type equivalent  
12 sandgrain roughness,  $k_s$ , as defined in the Colebrook-White (C-W) equation:  
13  
14  
15  
16

$$17 \quad \frac{1}{\sqrt{\lambda}} = -2.00 \log \left( \frac{k_s}{3.7D} + \frac{2.51}{R\sqrt{\lambda}} \right) \quad (1)$$

18  
19 where  $D$  is the internal pipe diameter,  $R$  is Reynolds number ( $=\bar{U}D/\nu$ ; where  $\bar{U}$  is the area-  
20 averaged axial flow velocity, and  $\nu$  is kinematic viscosity ( $=\mu/\rho$ ; where  $\mu$  is dynamic viscosity  
21 and  $\rho$  is the specific density)), and  $\lambda$  is the Darcy-Weisbach friction factor:  
22  
23  
24

$$25 \quad \lambda = \frac{2gDS_f}{\bar{U}^2} \quad (2)$$

26  
27 where  $g$  is the acceleration due to gravity (i.e.  $9.81 \text{ ms}^{-2}$ ), and  $S_f$  is the friction slope or  
28 pressure gradient ( $=dH_f/dx$ ; where  $H_f$  is hydraulic headloss ( $=\Delta P/\rho g$ , where  $\Delta P$  is pressure  
29 drop) and  $x$  is the characteristic length scale (in the streamwise direction). Solving Eq. (1) for  
30  $k_s$  yields:  
31  
32  
33

$$34 \quad k_s = 3.7D \left( 10^{\frac{-1}{2\sqrt{\lambda}}} - \frac{2.51}{R\sqrt{\lambda}} \right) \quad (3)$$

35  
36 The mechanisms by which a biofilm interacts with a fluid along with its physical  
37 morphology are governed by the conditions under which it is grown (Stoodley, Dodds, Boyle,  
38 & Lappin-Scott, 1998a; Stoodley, Lewandowski, Boyle, & Lappin-Scott, 1998b). There is  
39 compelling evidence to suggest that flow hydrodynamics and nutrient availability are the two  
40 most influential factors governing biofilm development in pipelines (Stoodley et al., 1998a,  
41 Lauchlan, Forty, & May, 2005). However, in DN's where it is likely that sufficient nutrients  
42 would be available; flow hydrodynamics will be the primary controlling factor due to its  
43 potential to remove existing biofilms, and/or counteract further growth. Nonetheless, there is  
44 an inherent link between flow hydrodynamics and nutrient availability on biofilm  
45 development; and this is due to their combined influence on mass transfer and diffusion. The  
46 mass transfer and diffusion potential of a system is predominantly controlled by the level of  
47 turbulence in the flow (i.e.  $R$ ).  
48  
49  
50  
51  
52  
53  
54  
55

56 The prevailing conditions in a typical DN imply that the presence of a biofilm is  
57 realistically unavoidable. Consequently, the accurate assessment of a biofouled surface is  
58  
59  
60

imperative for efficient pipeline design and effective control strategies. However, this is not possible through the application of conventional design approaches which utilise traditional frictional relationships and roughness scales. In particular, in their current forms Eq. (1) and  $k_s$  have been deemed inadequate for biofouled surfaces (Barton, 2006; Lambert, Edwards, Howie, Gilio, & Quinn, 2009; Perkins, Henderson, Walker, Sargison, & Li, 2014). It has been widely suggested that the complex surface dynamics of a biofilm cannot be adequately defined by a single one-dimensional parameter, such as  $k_s$  (Andrewartha, 2010; Barton, 2006). However, as such a parameter (or series of parameters) has yet to be successfully formulated, the Nikuradse equivalent sandgrain height was used within this study to define  $k_s$ .

Lambert et al. (2009) used experimental observations on freshwater biofilms to obtain a modified C-W equation (Eq. (4)), which is aimed at addressing the inadequacy of Eq. (1), i.e.:

$$\frac{1}{\sqrt{\lambda}} = -\frac{1}{\sqrt{8.08\kappa}} \ln \left( \frac{k_s}{0.85D} + \frac{2.51}{R\sqrt{\lambda}} \right) \quad (4)$$

Lambert et al. (2009) found that for biofouled pipes, the von Kármán constant  $\kappa$ , which is a fundamental part of the Eq. (1), was non-universal, dependant on  $R$ , and lower than the conventional value (i.e.  $\kappa = 0.42$ ). Solving Eq. (4) for  $k_s$  yields:

$$k_s = 0.85D \left( e^{\frac{-1\sqrt{8.08\kappa}}{\sqrt{\lambda}}} - \frac{2.51}{R\sqrt{\lambda}} \right) \quad (5)$$

Similar observations were reported by Perkins et al. (2014) for biofilms incubated in a hydropower system. However, these studies assessed a very specific set of environmental conditions; and in the case of Lambert et al. (2009), a very limited range of flow regimes (at low  $R$  values). Furthermore, the environmental conditions in a hydropower or freshwater system are inherently different to those found in DNs; and this would be reflected in the respective system's biofilm. This ultimately affects the broader application of the reported observations, particularly with respect to DNs. Nonetheless, the existence of a non-universal log-law is not a new concept, as there is debate within the classical theory as to whether  $\kappa$  is truly independent of  $R$  (Wei, Schmidt, & McMurtry, 2005). The highly dynamic nature of a biofouled surface will undoubtedly add an additional layer of complexity to the debate. The implication of a non-universal  $\kappa$  on roughness and flow rate determination (using Eq. (1)) could be considerable. This would be reflected in pipeline design through pipe sizing; and this could have financial and environmental implications especially if the pipe is oversized as a result (Cowle, Babatunde, Rauen, & Bockelmann-Evans, 2014). The impact of a non-universal  $\kappa$  would also be detrimental to wall similarity techniques, particularly with respect to their ability to effectively establish the local roughness for biofouled surfaces. This is

1  
2  
3 because these techniques which are commonly used to determine parameters such as wall  
4 shear velocity  $u_*$  by fitting experimental data to the law of the wall (Eq. (6)), are reliant on  
5 the existence of a universal log-law:  
6

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln(Y^+) + B$$

7  
8  
9  
10  
11 or 
$$\frac{u}{u_*} = \frac{1}{\kappa} \ln(Y^+) + 5.6 - \Delta U^+ \quad (6)$$

12  
13 where  $u$  is the local mean velocity,  $Y^+$  is the normalised wall distance ( $=u_*y/\nu$ , where  $y$  is the  
14 wall distance),  $B$  is Nikuradse's roughness function which assumes different values  
15 depending on the flow regime (for fully rough flow  $B = 8.48$ ), and  $\Delta U^+$  is the roughness  
16 function which represents the shift in the velocity profile from the smooth wall profile, and  
17 increases with increasing surface roughness. As a result, the frictional data derived from wall  
18 similarity techniques are highly sensitive to  $\kappa$  (Wei et al., 2005). The current prevailing  
19 understanding of biofilm-flow interactions is predominantly based upon observations  
20 established from wall similarity techniques, and thus a universal log-law (Andrewartha, 2010;  
21 Barton, 2006; Walker et al., 2013). The potential non-universality of  $\kappa$  could bring the  
22 conclusions of these studies into question.

Ultimately, the inadequacies in current design practices and hydraulic theory are a  
reflection of the current state of scientific understanding of biofouling in DN's (Cowle et al.,  
2014). The increasing awareness and emphasis on sustainability within the water industry,  
with respect to both the capacity and efficiency of existing networks and future installations,  
means that it is now more important than ever to change the perception of biofouling and  
address the inadequacies in current pipe design approaches.

The aim of this study was to evaluate the impact of biofouling on the surface  
roughness of a drainage pipe within a controlled laboratory environment. This would provide  
a platform through which the inadequacies in current pipe design approaches could be  
addressed. To this effect, the specific objectives of the study were to comprehensively  
determine the impact of biofouling on surface roughness and mean-velocity; investigate the  
impact of flow shear on biofilm development; and examine whether  $\kappa$  is non-universal for  
biofouled pipes.

## 2 Material and methods

### 2.1 Experimental facility

The experiments reported herein were conducted in a purpose built pilot scale pipeline  
facility, located in the Hydraulics Laboratory, at Cardiff University School of Engineering.  
The facility was designed and developed as an open loop, recirculating system for the specific

1  
2  
3 purpose of studying biofilm-flow interaction in DNs, over a wide range of flow conditions. It  
4 was fabricated mainly from high density polyethylene (HDPE), and it consisted of a storage  
5 tank (350 l), working and recirculation parts. The fluid in the pipeline was recirculated by a  
6 2.25 kW single phase centrifugal water pump (*Clarke CPE30A1*). The pump is capable of  
7 operating over the range of  $0.3 \text{ ms}^{-1} < \bar{U} < 1.3 \text{ ms}^{-1}$  (or  $3.0 \times 10^4 < R < 1.30 \times 10^5$ , based on a  
8 fluid temperature of  $20^\circ\text{C}$ ). The fluid temperature in the system was maintained by an external  
9 cooling unit (*D&D, DC-750*), and it was measured by two universal temperature probes  
10 (model: *LabJack EI-1034*). The probes had a typical accuracy of  $\pm 0.22^\circ\text{C}$  at room  
11 temperature, and they were calibrated under non-flow and flow conditions using a mercury  
12 thermometer which had an accuracy of  $\pm 0.10^\circ\text{C}$ . Temperature control is essential in both  
13 biofilm and boundary layer investigations, for the purpose of environmental and R control.  
14 The fluid temperature in the facility was maintained at  $21.5 \pm 0.9^\circ\text{C}$  and this is representative  
15 of the temperature found in typical European DNs during the summer (i.e.  $18\text{-}22^\circ\text{C}$ ) (Cipolla  
16 & Maglionico, 2014).  
17

20  
21  
22  
23  
24

25  
26 *[Insert Fig. 1]*  
27  
28

29 The working part of the facility was 9.5 m in length and it consisted of a test pipe (8.5  
30 m) and a visualisation pipe (1.0 m). The test pipe comprised of four individual solid wall high  
31 density polyethylene (S-HDPE) pipe segments. The discrete pipe segments were carefully  
32 aligned and connected by flexible pipe coupling in a way that ensures a smooth transition  
33 between the segments. Nonetheless, it was inevitable that the joints would cause some  
34 disruption to the velocity fields in the system. An S-HDPE pipe was selected due to its  
35 extensive use in the water industry, especially within the UK and modern projects. The inner  
36 diameter of the test pipe was measured at 8 axial locations and at 6 different positions along  
37 the length of the pipeline. The inner diameter was determined to be  $102.08 \pm 0.44 \text{ mm}$ .  
38  
39  
40  
41  
42  
43  
44

45  
46 *[Insert Fig. 2]*  
47  
48

49 As shown in Fig. 2, the test pipe consisted of a run-in section and a test section. The  
50 run-in section was 3.35 m (or  $34 D$ ) long and it corresponded to the region of  $0.00 \text{ m} < x <$   
51  $3.35 \text{ m}$ . Using the criteria outlined by Zagarola and Smits (1998), the length of the run-in  
52 section was deemed sufficient for fully developed mean flow to be obtained in the test  
53 section. The test section was 5.0 m in length and was located between  $3.35 \text{ m} < x < 8.35 \text{ m}$ .  
54

55 A hydrodynamic evaluation of the test pipe under non-fouled conditions over the  
56 range of  $3.15 \times 10^4 < R < 1.23 \times 10^5$  indicated that it had a  $k_s$  value of 0.01 mm. A surface is  
57 considered hydraulically smooth if the roughness Reynolds number,  $k_s^+ (=k_s v/u_*)$  is less than  
58  
59  
60

1  
2  
3 or equal to five (Nikuradse, 1933). The maximum value of  $k_s^+$ , which corresponds to the  
4 maximum  $R$  investigated (i.e.  $R = 1.23 \times 10^5$ ) was found to be 0.51. Consequently, the test  
5 pipe was considered to be hydraulically smooth.  
6  
7

## 8 9 2.2 Measurements and instrumentation

### 10 11 *Volumetric flow rate*

12  
13 The volumetric flow rate in the facility was recorded using a “time of flight” ultrasonic  
14 flowmeter (Nixon CU100). The meter had a reading accuracy of  $\pm 1.5\%$  and it was located in  
15 the recirculation part of the system. The flow rate,  $Q$  recorded by the ultrasonic flowmeter  
16 was verified against the  $Q$  values established from local mean-velocity data using a Pitot  
17 probe and conservation of mass principles. The diameter of the Pitot probe,  $d_p$  ( $=1.0$  mm)  
18 used to measure the mean-velocity data limited the spatial resolution near the wall to  
19 approximately 0.5 mm. Consequently, a near wall correction was required, especially for high  
20  $R$  values (Zagarola, 1996). The values of  $Q$  determined from the flowmeter and Pitot probe  
21 were found to have a strong correlation, with a coefficient of determination  $R^2$  of 0.92.  
22  
23  
24  
25  
26  
27

### 28 29 *Pressure gradient*

30  
31 As the flow in the test section was fully developed, the frictional resistance of the pipe can be  
32 accurately determined from the system’s pressure gradient (PG) by applying simple  
33 equilibrium considerations. The test section’s PG was measured using a series of static wall  
34 tappings located at various circumferential and longitudinal positions as shown in Fig. 2. In  
35 order to minimise the impact of the wall tappings on the external flow field, the tappings were  
36 designed in accordance with the recommendations outlined by McKeon and Smits (2002).  
37 The key size characteristics of the wall tappings were  $d_h = 0.75$  mm,  $d_h/D = 7.35 \times 10^{-3}$ ,  $l_h = 7.0$   
38 mm,  $l_h/d_h = 9.3$ ,  $d_c = 2.5$  mm and  $d_c/d_h = 3.33$ ; where  $d_h$  is the wall tappings’ diameter,  $l_h$  is the  
39 wall tappings’ length and  $d_c$  is the diameter of the connection to pressure gauge.  
40  
41  
42  
43  
44

45 Four wall tappings linked in a pressure ring arrangement were located at five  
46 streamwise locations (i.e.  $P_1, P_2, P_3, P_4, P_5$ , as shown in Fig. 2) along the test section. The  
47 pressure ring arrangement allowed a circumferential average pressure to be determined at  
48 each location; this reduced potential errors caused by uneven and unstable flow distributions  
49 (Barton, 2006). During a typical PG traverse, the time-averaged static pressure at each of the  
50 five streamwise locations was recorded at least 4 times and an average value determined. The  
51 wall tapping correction criteria outlined by McKeon and Smits (2002) was applied to all static  
52 pressure measurements recorded within the study.  
53  
54  
55  
56  
57  
58  
59  
60

### *Local velocity measurements*

A Pitot probe located at  $P_5$  (i.e.  $x = 8.35$  m) was used to obtain all time-averaged velocity profile traverses within the test pipe. The probe's aperture was square ended and 1.0 mm in diameter; and it was located in the same plane as the wall tapings at  $P_5$ . However, the main body of the probe was offset from the plane by 30.0 mm in a downstream direction; and this minimised any potential flow disruptions caused by the probe. A watertight gland allowed the probe to freely traverse 93% of the pipe's vertical plane. A wall origin,  $y = 0$ , was chosen at the invert side of the pipe. The distance along the pipe's vertical centreline relative to the wall origin was accurately determined using a digital height gauge (*Rapid AK9636D*), which had an accuracy of  $\pm 0.01$  mm. A typical velocity traverse consisted of at least 45 logarithmically spaced wall-normal positions. Several corrections were applied to all pressure measurements recorded by the Pitot probe and static wall tapping to account for the effects of viscosity, velocity gradient, the presence of the wall, and turbulence (McKeon, Li, Jiang, Morrison, & Smits, 2003).

The wall similarity technique outlined by Perry and Li (1990) – referred to herein as the PL method – was used to determine the local frictional conditions at  $P_5$ . The PL method has been used to evaluate biofouled surfaces (Andrewartha, 2010; Walker et al., 2013), and it is known to consistently produce highly accurate values of local  $u_*$  (Walker, 2014). The von Kármán constant applied during this analysis was 0.42. The Nikuradse's roughness function was determined using the procedure outlined by Ligami and Moffat (1986). To establish  $u_*$  using the PL method, the exact location of the wall must be known. However, this was difficult to achieve given the position of the probe within the test pipe. Consequently, a wall origin correction,  $\varepsilon$ , was applied. An adaptation of the method proposed by Perry and Joubert (1963) was integrated into the PL method in order to solve for  $\varepsilon$  and  $u_*$  simultaneously using an iterative approach.

### *Pressure transducers and data acquisition*

All pressure measurements were obtained using three high accuracy pressure transducers (*Omega PXM409-070HG10V*), designated 1 to 3; all of which had a full scale accuracy (including effects of linearity, hysteresis and repeatability) of  $\pm 0.08\%$  (or  $\pm 0.57$  mmH<sub>2</sub>O (at 20°C)). The pressure transducers were regularly calibrated to within  $\pm 0.5$  mm using individual wall mounted water manometers. Transducers 1 and 2 were used to record the pressure measurements required for each of the PG and velocity profile traverses. Transducer 3 always recorded the static pressure at location  $P_1$  during each of the respective traverses; for the purpose of removing any temporal variations observed during testing.

1  
2  
3 For each measurement interval within each of the PG and velocity profile traverses;  
4 the pressure, temperature and flow rate were simultaneously recorded by their respective  
5 devices and streamed to a desktop PC at a frequency of 100 Hz using a multifunction 24-bit  
6 datalogger (*LabJack U6-Pro*). Appropriate sampling times were derived for each of the  
7 variables using a cumulative time-averaged approach. For each discrete measurement, a  
8 setting time of 30 s and an acquisition time of 24 s was used to ensure transients had settled,  
9 and accurate time averaged pressure measurements could be attained.  
10  
11  
12  
13

### 14 2.3 Operating conditions

15  
16  
17 Biofilms were incubated in the facility with a synthetic wastewater under full bore and steady  
18 state conditions within three separate flow regime assays, namely: the  $R = 5.98 \times 10^4$  (or  $\bar{U} =$   
19  $0.60 \text{ ms}^{-1}$ ) assay;  $R = 7.82 \times 10^4$  (or  $\bar{U} = 0.75 \text{ ms}^{-1}$ ) assay; and  $R = 1.00 \times 10^4$  (or  $\bar{U} = 1.00 \text{ ms}^{-1}$ )  
20 assay. The flow conditions within the respective assays are common in DNs in the UK,  
21 particularly in pumping/force mains which typically operate full bore and between the range  
22 of  $0.6 \text{ ms}^{-1} < \bar{U} < 1.0 \text{ ms}^{-1}$  (Lauchlan et al., 2005). The maximum recorded variation in  $R$  was  
23  $\pm 3\%$ , this indicates that the flow conditions within the respective assays were reasonably  
24 homogenous. The shear stress,  $\tau_w$  acting on the biofilm was  $\tau_w = 1.42 \text{ Nm}^{-2}$  for the  $R =$   
25  $5.98 \times 10^4$  assay,  $\tau_w = 2.15 \text{ Nm}^{-2}$  for the  $R = 7.82 \times 10^4$  assay, and  $\tau_w = 2.95 \text{ Nm}^{-2}$  for the  $R =$   
26  $1.00 \times 10^4$  assay. These values are based upon the initial conditions (i.e. without fouling) and  
27 the principle that the primary force acting on the biofilm was the shear force generated by the  
28 flow (Stoodley, Cargo, Rupp, Wilson, & Klapper, 2002). The internal hydraulic retention  
29 time in the facility during the three flow assays was at least 73 s and therefore the systems  
30 were considered to be well-mixed.  
31  
32  
33  
34  
35  
36  
37  
38

39 The synthetic wastewater was prepared according to the specification outlined by the  
40 Organisation for Economic Cooperation and Development (OCED, 1984), which provided  
41 nutrient conditions that are representative of those found in typical DNs in Europe. The  
42 wastewater had the following composition:  $320 \text{ mg l}^{-1}$  of Peptone;  $220 \text{ mg l}^{-1}$  of meat extract  
43 ( $540 \text{ mg l}^{-1}$  as Chemical Oxygen Demand (COD));  $30 \text{ mg l}^{-1}$  of Urea ( $\text{CH}_4\text{N}_2\text{O}$ ) ( $50 \text{ mg l}^{-1}$  as  
44 Total Nitrogen, (TN));  $12 \text{ mg l}^{-1}$  of di-potassium hydrogen phosphate ( $\text{KH}_2\text{PO}_4$ ) ( $10 \text{ mg l}^{-1}$  as  
45 Total Phosphorus (TP));  $7 \text{ mg l}^{-1}$  of sodium chloride,  $4 \text{ mg l}^{-1}$  of Calcium Chloride Dihydrate  
46 ( $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ ); and  $2 \text{ mg l}^{-1}$  of Magnesium Sulfate Heptahydrate ( $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ ). The pH,  
47 Total Organic Carbon (TOC) and Dissolved Organic Carbon (DOC) of the prepared wastewater  
48 was  $7.95 \pm 0.15$ ,  $244 \text{ mg l}^{-1}$  and  $201 \text{ mg l}^{-1}$ , respectively. The physico-chemical properties of  
49 the wastewater within the three flow assays are presented in Table 1.  
50  
51  
52  
53  
54

55 The three flow assays ran for 20 d (480 h). Based on the nutrient conditions, this was  
56 deemed sufficient for the biofilms to reach a state of equilibrium, at least in terms of their  
57  
58  
59  
60

1  
2  
3 frictional resistance (Andrewartha, 2010; Lambert et al., 2009). Prior to the experimental  
4 work, the entire facility was disinfected using a concentrated chlorine solution, and sodium  
5 thiosulfate was used to neutralise any residual chlorine in the facility post disinfection.  
6  
7

8  
9  
10 *[Insert Table 1]*

#### 11 12 *2.4 Experimental uncertainty*

13  
14 The uncertainties associated with the friction parameters measured and calculated within the  
15 current study are given in Table 2. The uncertainties were determined from repeatability test  
16 and they represent a 95% confidence interval. The repeatability tests were undertaken under  
17 non-fouled conditions over the range of  $3.15 \times 10^4 < R < 1.23 \times 10^5$  (at increments of  $R \approx$   
18  $1.00 \times 10^4$ ). Each  $R$  increment included a PG and velocity profile traverse and was repeated at  
19 least three times.  
20  
21  
22  
23

24  
25  
26 *[Insert Table 2]*

27  
28 The uncertainties listed in Table 2 for the non-fouled pipe represent the worst case  
29 conditions for the facility; and this was due to the smoothness of the non-fouled pipe and the  
30  $R$  values assessed. Higher Reynolds numbers, i.e. in excess of  $R = 1.30 \times 10^5$  which would  
31 have improved the experimental uncertainties listed in Table 2 could not be achieved using  
32 the facility in its current arrangement. Similarly, a test section with a greater overall length  
33 which could also have improved the experimental uncertainties, could not be achieved due to  
34 laboratory restrictions.  
35  
36  
37  
38

### 39 **3 Results and discussion**

#### 40 41 42 *3.1 General description of fouled pipes*

43  
44 The biofilms incubated with synthetic wastewater within the current study displayed a  
45 predominantly low-form gelatinous structure. Filamentous type development was observed  
46 but very rarely, with filaments seldom exceeding 10 mm. The fouled pipes showed various  
47 amounts of microbial material with very different morphologies depending on the  
48 conditioning. Typically, the biofilm incubated at high shear (i.e. in the  $R = 1.00 \times 10^5$  assay)  
49 had a seemingly more uniform coverage than the biofilm incubated at low shear (i.e. in the  $R$   
50  $= 5.98 \times 10^4$  assay), which had a more isolated structure. Molecular analysis of the biofilms  
51 showed that they were diverse arrays of microbial cells, embedded within an extracellular  
52 polymer matrix of which carbohydrates dominated. Polymerase Chain Reaction-Denaturing

56  
57  
58  
59  
60

1  
2  
3 Gradient Gel Electrophoresis (PCR-DGGE) indicated that the biofilms were dominated by  
4 *Bacteria* and in particular, members of the phyla *Alphaproteobacteria*, *Betaproteobacteria*,  
5 *Actinobacteria*, *Bacteroidetes* and *Firmicutes*. These species are commonly found in DNAs and  
6 as a result, the biofilms were considered representative of those found in real systems, at least  
7 in terms of bacterial dominance (Santo Domingo, Revetta, Iker, Gomez-Alvarez, Garcia,  
8 Sullivan, & Weast, 2011).  
9  
10  
11

### 12 3.2 Impact on frictional resistance

13  
14 A complete set of PG and mean-velocity traverses were taken at least 3 times a day during  
15 each of the biofilm incubation phases, with the exception of the  $R = 7.82 \times 10^4$  assay where  
16 only PG data was collected. A total of 60 PG and mean-velocity (if applicable) profiles were  
17 taken during the incubation phase of three flow assays. The influence of biofilm development  
18 on frictional resistance in the form of  $\lambda$  over time  $t$  is depicted in Fig. 3. The values of  $\lambda$   
19 presented in Fig.3 for the three flow assays were determined from the system's PG using Eq.  
20 (2), where  $S_f$  was derived from a linear fit of the profiles of static pressure and therefore, it  
21 represents the space-averaged conditions over the entire test section. The static pressure  
22 profiles recorded within this study for all the fouled pipes, at all flow rates and time intervals  
23 were always a linear function.

25  
26  
27  
28  
29  
30  
31

32 [Insert Fig. 3]

33  
34  
35 The increase in frictional resistance, as indicated by the increase in  $\lambda$  caused by the  
36 biofilm development was significant, particularly with respect to the initial non-fouled  
37 conditions. This is consistent with the findings outlined previously within the literature  
38 (Barton et al., 2008). The observed increases in frictional resistance would have potentially  
39 resulted in a reduction in  $Q$  of between 15-22% had the pressure drop been held constant in  
40 each of the respective flow assays. It is evident from Fig. 3 that  $\lambda$  begins to depart from the  
41 non-fouled value after just 25 h of incubation. The biofilms reached a state of equilibrium, in  
42 terms of their frictional development after approximately 180 h (see Fig. 3). A summary of  
43 the frictional conditions recorded after the biofilms had reached a state of equilibrium is  
44 presented in Table 3, where  $c_f$  is the skin friction coefficient. The values of  $k_s$  presented in  
45 Table 3 were determined using the traditional C-W equation (i.e. Eq. (3)) and therefore, they  
46 should be viewed with caution as a result of the equation's documented inadequacies in  
47 evaluating biofouled surface (as discussed previously in section 1).

It is evident from Table 3 and Fig. 3 that the highest values of  $\lambda$  were measured in the  $R = 5.98 \times 10^4$  assay where  $\lambda$  plateaued at 0.034. The lowest values of  $\lambda$  were measured in the  $R = 1.00 \times 10^5$  assay where  $\lambda$  plateaued at 0.026. The  $R = 7.82 \times 10^4$  assay represented the intermediate. Single factor analysis of variances (ANOVAs) conducted on the three flow assay datasets indicated that the differences in  $\lambda$  between the respective assays were statistically significant, within the experimental uncertainty. The significance level of all ANOVAs was set at  $\alpha = 0.05$ .

Dimensionless mean-velocity profiles are presented in Fig. 4 for the range of  $0 \leq (y+\varepsilon) \leq r$  (where  $r$  is the pipe radius ( $=D/2$ )). It can be seen that the biofilms caused a gradual shift in the velocity profiles associated with increasing surface roughness. This is in agreement with observations of Walker et al. (2013) for biofilms incubated in a hydropower channel for between 2-52 weeks, at  $\bar{U} \approx 1.0 \text{ ms}^{-1}$ . Once the biofilms had reached a state of equilibrium, the respective profiles appeared to collapse well onto a single curve (see Fig. 4c). Varying degrees of roughness can be observed in Fig. 4; and typically, the biofilm cultivated in the  $R = 5.98 \times 10^4$  assay had the greatest influence on roughness, as exhibited by the greatest shift away from the non-fouled data. The mean-velocity data is presented in velocity defect form in Fig. 5. It is evident from Fig. 5 that the non-fouled and fouled data collapsed well onto a single curve in the outer region of the boundary layer. This suggests that the presence of a biofilm did not affect the mean-flow structure in the outer region and therefore it provides support for Townsend's wall similarity hypothesis. This has also been observed within the literature for freshwater and marine biofilms (Walker et al., 2013).

[Insert Fig. 4]

[Insert Fig. 5]

It is evident that the frictional resistance induced by a biofilm is a function of the biofilm's conditioning. In particular, the lower the conditioning  $R$ , the greater the frictional resistance imposed by the biofilm. This is to be expected, as the overall thickness of a biofilm is heavily dependent on the shear conditions in which it is incubated; and typically, the higher the conditioning shear the thinner the biofilm (Barton, 2006; Celmer, Oleszkiewicz, Cicek, 2008). As a biofilm's thickness defines to some extent the physical and effective roughness of a biofouled surface, the thinner the biofilm, the lower the frictional resistance expected (Andrewartha, 2010; Barton, 2006). Naturally, the opposite is true of thicker biofilms.

Furthermore, the mass transfer and drag limitation potentials associated with lower  $R$  values would typically foster a more isolated and irregularly distributed biofilm (Stoodley et

1  
2  
3 al., 1998a). Such a roughness distribution would induce a higher overall frictional resistance  
4 than that imposed by a uniformly distributed structure (Andrewartha, 2010; Stoodley et al.,  
5 2002). This could further explain the relatively high nature of the frictional data recorded in  
6 the  $R = 5.98 \times 10^4$  assay. Alternatively, the increased mass transfer and diffusion potentials  
7 associated with higher  $R$  values would have induced a more uniformly distributed biofilm  
8 (Celmer et al., 2008; Stoodley et al., 2002). The increased uniformity coupled with the limits  
9 imposed on maximum thickness by the inherently high drag could explain the low values of  $\lambda$   
10 recorded in the  $R = 1.00 \times 10^5$  assay.  
11

12 The irregularity of the biofilm's space-averaged roughness distribution was evaluated  
13 by examining each part of the test section discreetly (i.e.  $P_1$ - $P_5$ ,  $P_1$ - $P_4$ ,  $P_1$ - $P_3$  etc.). Figure 6  
14 illustrates the standard deviation in  $\lambda$  for the  $R = 5.98 \times 10^4$  and  $R = 1.00 \times 10^5$  assays. The  
15 average standard deviation in  $\lambda$  determined under non-fouled conditions of  $1.25 \times 10^3$  is also  
16 presented in Fig. 6 for reference purposes. It is evident from Fig. 6 that the variation in space-  
17 averaged conditions along the test section after the biofilms had reached a state of  
18 equilibrium, was far greater in the  $R = 5.98 \times 10^4$  assay than in the  $R = 1.00 \times 10^5$  assay. This  
19 was supported by single factor ANOVAs conducted on the respective flow assays (where  $\alpha =$   
20 0.05) which indicated that the differences in the values of  $\lambda$  recorded along the test section in  
21 the  $R = 5.98 \times 10^4$  assay were statistically significant, whereas the ANOVAs performed on the  
22  $R = 1.00 \times 10^5$  assay data showed that the differences in values of  $\lambda$  were statistically  
23 insignificant. The observed variations in the space-averaged values of  $\lambda$  supports the  
24 assumption that biofilm's overall coverage in the  $R = 5.98 \times 10^4$  assay was more irregular and  
25 thus less uniform (over the length of the system), than the respective coverage in the  $R =$   
26  $1.00 \times 10^5$  assay. The observed heterogeneity of a biofilm's roughness serves to highlight the  
27 problem of characterising a biofilm's effective roughness using a single scale, i.e.  $k_s$ .

### 47 3.3 Influence of Reynolds number on mature biofilm development

48 Once the biofilms incubated in the  $R = 5.98 \times 10^4$  and  $R = 1.00 \times 10^5$  assays had reached a state  
49 of equilibrium in terms of their frictional resistance, they were subjected to varying flow  
50 regimes (over the range of  $3.05 \times 10^4 < R < 1.23 \times 10^5$ ). A total of 10  $R$  increments were  
51 assessed within this phase which will be referred to as the mature testing phase. A complete  
52 set of PG and mean-velocity traverses were recorded for each of the fouled pipes at each  $R$   
53 increment. A total of 62 PG and mean-velocity profiles were recorded during the mature  
54 testing phase. This took place after approximately 480-500 h of incubation, and it lasted for  
55  
56  
57  
58  
59  
60

1  
2  
3 about 12-15 h. An unforeseen complication which led to the death of the biofilm incubated in  
4 the  $R = 7.82 \times 10^4$  assay prior to the 500 h mark precluded it from this phase of testing.  
5

6 The influence of  $R$  on  $\lambda$  is illustrated in Fig. 7. The relationships between  $R$  and  $\lambda$   
7 depicted in Fig. 7 for the respective fouled pipes are evidently different to that expected based  
8 on standard convention (i.e. Eq. (1)). In particular, it is evident from Fig. 7 that  $\lambda$  increases  
9 with increasing  $R$ . For the  $R = 5.98 \times 10^4$  assay,  $\lambda$  increased to a maximum of  $3.34 \times 10^{-3}$  at  $R =$   
10  $9.02 \times 10^4$ ; whereas for the  $R = 1.00 \times 10^5$  assay,  $\lambda$  increased to a maximum of  $2.74 \times 10^{-3}$  at  $R =$   
11  $9.61 \times 10^4$ . Consequently, the current study is in agreement with the general consensus that  $\lambda$   
12 for a biofouled surface does not follow the traditional C-W relationship (Barton, 2006).  
13  
14  
15  
16

17  
18 [Insert Fig. 7]  
19

20  
21 The degree at which  $\lambda$  increases with  $R$  is seemingly a function of the biofilm's  
22 overall effective roughness (and thus its roughness distribution). In particular, the greater the  
23 roughness, the greater the increase in  $\lambda$ . Lambert et al. (2009) reported a similar phenomenon  
24 for biofouling, albeit for smaller diameter pipes (i.e.  $D = 25$ -50 mm).  
25  
26

27 Once the local maximum was reached,  $\lambda$  begins to decrease with increasing  $R$ . In the  
28 case of the  $R = 5.98 \times 10^5$  assay, this decrease was significant; whereas the equivalent decrease  
29 in the  $R = 1.00 \times 10^5$  assay was far more gradual. Similar trends have been reported within the  
30 literature (Barton et al., 2008; Lambert et al., 2009; Perkins et al., 2014). For instance, Perkin  
31 et al. (2014) found that the  $\lambda$  of a biofilm incubated in a hydropower pipeline increased  
32 gradually with increasing  $R$  between  $9.32 \times 10^4 < R < 1.57 \times 10^5$ , to a maximum of 0.033,  
33 before decreasing significantly with increasing  $R$  between  $1.57 \times 10^4 < R < 2.66 \times 10^5$ . The  
34 biofilm assessed by Perkin et al. (2014) was conditioned at  $\bar{U} = 1.30 \text{ ms}^{-1}$ . The evident  
35 reduction in  $\lambda$  with  $R$  after the local maximum was reached could be explained by a reduction  
36 in biofilm thickness caused by the biofilm compressing itself under loading (Percival, Knapp,  
37 Wales, & Edyeyan, 1999), or by it being sheared from the surface (Andrewartha, 2010;  
38 Barton, 2006). The usual reduction in  $\lambda$  with  $R$  could also explain the evident trend (Perkin et  
39 al., 2014).  
40  
41  
42  
43  
44  
45  
46

47 The concentration of TOC in the bulk water was measured at each  $R$  increment to  
48 indirectly determine whether the increase in flow shear could actively remove the biofilm  
49 from the surface. Bulk water samples were taken directly from the storage tank and stored at  
50  $20^\circ\text{C}$  before being analysed. Due to the relatively short time it took to complete each of the  
51 mature testing phases (i.e.  $< 15$  h), any changes in water chemistry during this phase would  
52 have likely been caused by biofilm detachment. The concentrations of TOC recorded in the  
53 bulk water for the  $R = 5.98 \times 10^5$  and  $R = 1.00 \times 10^5$  assays is presented in Fig. 8. It is evident  
54 from Fig. 8 that the concentration of TOC increased significantly in the  $R = 5.98 \times 10^4$  assay as  
55  
56  
57  
58  
59  
60

1  
2  
3 flow shear increased. In particular, a significant increase in TOC was evident when  $R$   
4 exceeded  $6.54 \times 10^4$ . The equivalent increase was less extreme in the  $R = 1.00 \times 10^5$  assay,  
5 although an increase was evident when  $R$  exceeded  $9.60 \times 10^4$ . The observed increases in  
6 organic content in each assays' bulk water suggests that biofilm detachment was likely to  
7 have occurred. However, based on the magnitude of the respective increases, the degree of  
8 detachment will have varied between the assays. For instance, the concentration of TOC in  
9 the bulk water of the  $R = 5.98 \times 10^4$  assay following the increase in flow shear was  $62.5 \text{ mg l}^{-1}$ ,  
10 whereas the equivalent concentration in the bulk water of the  $R = 1.00 \times 10^5$  assay was  $10.9$   
11  $\text{mg l}^{-1}$ . Therefore, it could be suggested that greater biofilm detachment was likely to have  
12 occurred in the  $R = 5.98 \times 10^4$  assay than in the  $R = 1.00 \times 10^5$  assay. The presumed detachment  
13 point for the  $R = 1.00 \times 10^5$  assay's biofilm, as suggested by the increase in bulk water organic  
14 content, is the same point at which a reduction in  $\lambda$  was first recorded (see Fig. 7).  
15

17  
18  
19  
20  
21  
22

23 *[Insert Fig. 8]*  
24  
25

26 The gradual reduction in  $\lambda$  combined with the relatively low increase in TOC with  $R$ ,  
27 which was observed in the  $R = 1.00 \times 10^5$  assay, could potentially suggest that the respective  
28 biofilm was merely thinned and/or compressed by the increase in flow shear. Alternatively,  
29 the considerable changes in  $\lambda$  and TOC observed in  $R = 5.98 \times 10^4$  assay, would suggest that  
30 large scale detachment occurred in the respective assay. However, as  $\lambda$  did not approach the  
31 non-fouled curve post shear, it was unlikely that the biofilm was completely removed. The  
32 point at which  $\lambda$  began to decrease with  $R$  in the  $R = 5.98 \times 10^4$  assay did not coincide with the  
33 detachment point implied by the changes in bulk water chemistry (i.e.  $R > 6.54 \times 10^4$ ). In fact,  
34  $\lambda$  continued to increase beyond this presumed detachment point; and this suggests that biofilm  
35 detachment did not occur. However, it is possible that the initial detachment which gave rise  
36 to the increases in bulk water organic content had a negligible effect on the biofilm's  
37 frictional capacity. Conversely, it is equally possible that the initial biofilm detachment could  
38 have given rise to a more heterogeneous roughness distribution, which could have directly  
39 contributed to, or be the reason for the observed  $\lambda$  relationship.

### 49 3.4 Determining $\kappa$ for biofouled surfaces

50 The von Kármán constant's dependence on  $R$  was assessed using the PG and mean-velocity  
51 data recorded during the mature testing phase. In particular, a linear regression line of best fit  
52 was fitted to the log-law region of  $U^+$  against  $\ln((y+\epsilon)/k_s)$  plot. The inverse of the slope of this  
53 regression line was equal to  $\kappa$  (i.e.  $\kappa = 1/[d(U^+)/d(\ln((y+\epsilon) u_* / \nu))]$ ). The location of the log-law  
54 region within the boundary layer was determined experimentally using the method outlined  
55  
56  
57  
58  
59  
60

1  
2  
3 by Saleh (2005), and it was found to be unaffected by the presence of a biofilm. The location  
4 of the log-law region was taken as  $50 < yu_*/\nu < 0.18r^+$  ( $= r\nu/u_*$ ) which is also where standard  
5 convention states that it should be (George, 2007).  
6

7  
8 Wall similarity techniques, such as the PL method are typically used to determine  
9 local frictional conditions at a particular streamwise location from mean-velocity data.  
10 However, such techniques are inherently dependent on a universal log-law in which  $\kappa$  is a  
11 known constant and typically equal to 0.42. As  $\kappa$  is the unknown in this instance, wall  
12 similarity techniques cannot be applied. Therefore, with no other means of determining the  
13 local frictional data, the global data determined from the system's PG was used. In particular,  
14 the frictional data determined between  $P_3$  and  $P_5$  was applied in this case. It should be noted  
15 that although the global values of  $u_*$  were unaffected by  $\kappa$ , the global values of  $k_s$  required re-  
16 calculation using Eq. (5). This was an iterative process that typically required 3-4 iterations  
17 for a suitable convergence to be obtained.  
18  
19

20  
21  
22  
23 Despite the fact that the applied global data represents the frictional conditions for the  
24 section at which the mean-velocity data was recorded, it may not be a true reflection of the  
25 local frictional conditions at  $P_5$  (i.e. where the mean-velocity data was recorded). This is  
26 because a biofilm's roughness distribution is generally heterogenetic, as highlighted by the  
27 biofilm incubated in the  $R = 5.98 \times 10^4$  assay. Furthermore, although the biofilm incubated in  
28 the  $R = 1.00 \times 10^5$  assay displayed a seemingly uniform roughness distribution, it is still highly  
29 unlikely that it was truly homogeneous over the whole system. Any error in the frictional data  
30 used to determine  $\kappa$  would naturally result in errors in established values  $\kappa$  (Wei et al., 2005).  
31  
32 Consequently, the results presented herein should be viewed accordingly and with caution.  
33  
34

35  
36  
37 The relationship between  $\kappa$  and  $R$  is presented in Fig. 9 which illustrates the  
38 combined data measured in the two fouled pipes. As it was not possible to distinguish  
39 between the two fouled pipe's datasets, the two datasets were combined. It is evident from  
40 Fig. 9 that  $\kappa$  has a dependency on  $R$ , and in particular, a trend of increasing  $\kappa$  with increasing  
41  $R$  can be observed. The elastic nature of a biofilm may have contributed to these trends. The  
42 lowest value of  $\kappa$  was measured for  $R = 2.50 \times 10^5$  and it was equal to 0.32. The reduction in  $\kappa$   
43 from the conventional value lessened as  $R$  increased. This may have been as a result of the  
44 assumed biofilm detachment and the smoothening of the pipe's surface under loading. This is  
45 supported by the fact that the value of  $\kappa$  approaches the canonical value as  $R$  increases.  
46  
47  
48  
49

50  
51  
52 *[Insert Fig. 9]*  
53  
54

55 The relationship of  $\kappa$  with  $R$  was found to be a linear function ( $R^2 > 0.95$ ), as given  
56 by:  
57  
58  
59  
60

$$\kappa = 9.443 \times 10^{-7}R + 0.302 \quad (7)$$

The trend observed within the current study for  $\kappa$  is consistent with the findings of Perkins et al. (2014) and Lambert et al. (2009). However, the values of  $\kappa$  found within the current study were generally higher than the equivalent values reported by Perkins et al. (2014), who assessed the impact of biofouling on  $\kappa$  in a pipe with similar diameter to that used within the current study (i.e.  $D = 101.6\text{mm}$ ). Nonetheless, the biofilms observed by Perkins et al. (2014) had a significant filamentous component. Visually, the filaments pictured by Perkins et al. (2014) were considerably more abundant than those observed within the current study. Filamentous type development is known to induce a considerable amount of drag on a system, and it can alter the mean flow structure in the outer region of the boundary layer in some extreme cases (Andrewartha, 2010; Barton et al., 2006). However, as a result of the inherently dark conditions in a DN, it is unlikely that the filaments observed by Perkins et al. (2014) would have been as long as those reported in the extreme cases, which typically relate to biofilms incubated in open channels. Nevertheless, the interactions between the filaments and the fluid may have contributed to the lower values of  $\kappa$  observed by Perkins et al. (2014). Consequently, the degree and type of biofouling may have had a greater influence on  $\kappa$  than was first thought, based on the observations reported within this study.

The observed non-universality of  $\kappa$  means that as expected, the values of  $k_s$  derived using Eq. (3), and presented in Table 3 are unrepresentative of the actual conditions. The equilibrium state values of  $k_s$  as derived from Eq. (5) (where  $\kappa$  is defined by Eq. 7) for the  $R = 5.98 \times 10^4$  and  $R = 1.00 \times 10^5$  assays were  $0.11\text{mm}$  and  $0.08\text{mm}$ , respectively. Therefore, the traditionally derived  $k_s$  values (see Table 3) are significantly higher than those derived using the modified C-W equation. Nevertheless, although the magnitude of the  $k_s$  values may have changed, the influence of conditioning shear on biofilm induced  $k_s$  remained the same. Figure 10 presents the experimentally determined mature phase values of  $\lambda$  recorded in the  $R = 5.98 \times 10^4$  and  $R = 1.00 \times 10^5$  assays, along with theoretically determined values derived from Eq. (5) and (7). It is evident from Fig. 10 that prior to the local maximums being reached, the modified C-W curves established using Eq. (5) and (7) were in good agreement with the experimentally determined values of  $\lambda$ . In particular, it was found that the maximum discrepancy between the measured and predicted values was  $\pm 7.21\%$ . The average discrepancy between the respective values of  $\lambda$  was  $\pm 2.82\%$ . These discrepancies are within the experimental uncertainty in  $\lambda$  presented in Table 2.

*[Insert Fig. 10]*

1  
2  
3 The suggestion that wall similarity applies to biofouled pipes (i.e. as indicated by Fig.  
4 5) can also be questioned by the observed non-universality of  $\kappa$ . This is because the velocity  
5 defect plots presented in Fig. 5 were scaled by values of  $u_*$  derived from the PL method.  
6 Velocity defect plots, which have been scaled by values of  $u_*$  determined directly from the  
7 system's PG are presented in Fig. 11 for the  $R = 5.98 \times 10^4$  and  $R = 1.00 \times 10^5$  assay. The  
8 observed collapses of the non-fouled and fouled profiles suggest that wall similarity is valid  
9 for biofouled surfaces, irrespective of the non-universality of the log-law constants.

## 4 Conclusions and recommendations

### 4.1 Conclusions

Biofouling in drainage networks is realistically unavoidable. Therefore, the frictional properties of a biofilm, which are characterised by their highly dynamic and case-specific nature, should represent the “true” underlying surface roughness of all pipelines in service. However, such an understanding is currently not recognised within conventional design practices, and this is detrimental to efficient and sustainable operation given that:

- a biofilm has an inherent ability to induce an effective roughness which is well in excess of what its physical structure would traditionally suggest; and
- traditional frictional relationships fail to adequately account for the true nature of a biofouled surface in their current manifestation.

The current study has comprehensively evaluated the impact of biofouling on frictional resistance of a high density polyethylene drainage pipe. The finding of the study with regards to the influence of flow hydrodynamics on biofilm frictional development over time, have gone beyond that previously documented within the literature.

An initial increase in roughness caused by biofilm development was observed after just 25 h of incubation, and it continued to increase until a statistically steady state was achieved. The time at which the biofilms reached a state of equilibrium was found to be independent of the conditioning shear and equal to 180 h. The magnitude of a biofilm's frictional resistance was evidently a function of the shear conditions under which the biofilm was incubated. Most notably, it was found that the lower the conditioning shear, the higher the frictional resistance imparted by the biofilm. This is attributed to the thickness and roughness distribution induced by such conditions, and it serves to highlight the problem of

1  
2  
3 characterising a biofilm's effective roughness using a single roughness scale. A biofilm's  
4 impact on frictional resistance is further compounded by its influence over the von Kármán  
5 constant. In particular, the current study has provided conclusive evidence that the von  
6 Kármán constant for biofouled surfaces is non-universal, dependent on Reynolds number, and  
7 lower than the conventionally accepted value. As a consequence of the non-universality of the  
8 von Kármán constant, the traditional Colebrook-White equation is not applicable to biofouled  
9 pipes. The Darcy-Weisbach friction factor for a biofouled surface was shown to increase with  
10 increasing Reynolds number, until a critical threshold was reached. Thereafter, the Darcy-  
11 Weisbach friction factor decreased with increasing Reynolds number. This decrease was  
12 partly attributed to the biofilm becoming detached under loading. Changes in bulk water  
13 chemistry, and in particular organic content supported this assumption.

14  
15 A modified Colebrook-White equation (i.e. Eq. (3)) can be applied to drainage  
16 networks, provided the von Kármán constant is defined by Eq. (7). Furthermore, it was found  
17 that, although wall similarity is valid and applicable to biofouled surfaces, it is reliant on  
18 either the von Kármán constant or shear velocity being known, without which the results are  
19 likely to be unrepresentative of the actual conditions.

#### 20 21 22 23 24 25 26 27 28 29 *4.2 Recommendations for further research*

30  
31 The incubation conditions used within the current study were purposely designed to  
32 be representative of those found within natural sewer systems, albeit for those operating at  
33 full bore. The resultant biofilms incubated and evaluated within this study can therefore be  
34 considered equivalent to those found in real systems. However, wastewater systems with the  
35 exception of rising mains are rarely operated at full bore, and drainage networks as a whole  
36 are generally unsteady in nature. Consequently, although the study has provided much needed  
37 data on biofouling in DNS, further research is still required in order for biofouling to be truly  
38 incorporated in pipeline design practices. Such research should ideally expand on the  
39 fundamental ideas and concepts outlined within this study. In particular, it is recommended  
40 that biofilm development over time is evaluated for a greater range of conditions including a  
41 broader range of flow regimes, nutrient levels, operating depths and temperatures. Similarly,  
42 given the highly variable nature of real systems, it would be beneficial to incorporate and  
43 evaluate typical daily and seasonal variations in operational and environmental conditions  
44 within future studies. This study has however provided the platform and methodology needed  
45 for such future investigations to be achieved

guidance on the molecular analysis aspect of this study. The industrial insight and expertise provided by Dr Vasilios Samaras (Asset International Limited) should also be acknowledged. Furthermore, Dr William Rauen (Universidade Positivo, Brazil) and Professor Binliang Lin (Tsinghua University, China) must be accredited for the initial research concept. The authors would also like to thank the technical staff at the School of Engineering, Cardiff University, and in particular, Mr Len Czekaj and Mr Paul Leach for their support with the experimental work. Finally, the authors would like to thank Mr Mark Taylor (Mott MacDonald) for taking the time to review the manuscript.

### Funding

This work was supported by the UK Engineering and Physical Sciences Research Council (EPSRC) and Asset International Limited.

### Notation

$B$  = Nikuradse's roughness function

$c_f$  = local skin friction coefficient

$D$  = pipe diameter (mm)

$d_c$  = diameter of the pressure transducer connection tube (mm)

$d_h$  = wall tapping hole diameter (mm)

$d_p$  = Pitot Probe diameter (mm)

$g$  = gravity acceleration constant ( $\text{ms}^{-2}$ )

$h$  = hours

$H_f$  = hydraulic head (mm)

$k_s$  = Nikuradse-type equivalent sandgrain roughness (mm)

$L$  = streamwise Length (m)

$\Delta P$  = pressure drop ( $\text{Nm}^{-2}$ )

$Q$  = volumetric flow rate ( $\text{m}^3\text{s}^{-1}$ )

$r$  = pipe radius (mm)

$R^2$  = coefficient of determination

$R$  = Reynolds number

$S_f$  = friction slope

$T$  = temperature ( $^{\circ}\text{C}$ )

$t$  = time (h)

$\bar{U}$  = area-averaged axial velocity ( $\text{ms}^{-1}$ )

$u$  = local mean streamwise velocity ( $\text{ms}^{-1}$ )

$U^+$  = normalised velocity

1  
2  
3  $u_* =$  wall shear velocity ( $\text{ms}^{-1}$ )  
4  $\Delta U^+ =$  Hama's (1954) roughness function  
5  
6  $x =$  characteristic length scale  
7  
8  $y =$  distance from the wall (mm)  
9  
10  $\Delta =$  change in a variable  
11  $\varepsilon =$  wall origin error (mm)  
12  $\kappa =$  von Kármán constant  
13  $\lambda =$  Darcy-Weisbach friction factor  
14  
15  $\mu =$  dynamic viscosity ( $\text{Nm}^{-2}\text{s}$ )  
16  
17  $\rho =$  density ( $\text{kgm}^{-3}$ )  
18  
19  $\tau_w =$  wall shear stress ( $\text{Nm}^{-2}$ )  
20  
21  $\nu =$  kinematic viscosity ( $\text{m}^2\text{s}^{-1}$ )  
22  
23  $^+ =$  normalised by  $u_*$  or  $u_*/\nu$
