**Abstract**

In this paper, we present a novel and robust Bayesian approach for autonomous active exploration of unknown objects using tactile perception and sensorimotor control. Despite recent advances in tactile sensing, robust active exploration remains a challenging problem, which is a major hurdle to the practical deployment of tactile sensors in robots. Our proposed approach is based on a Bayesian perception method that actively controls the sensor with local small repositioning movements to reduce perception uncertainty, followed by explorative movements based on the outcome of each perceptual decision making step. Two sensorimotor control strategies are proposed for improving the accuracy and speed of the active exploration that weight the evidence from previous exploratory steps through either a weighted prior or weighted posterior. The methods are validated both off-line and in real-time on a contour following exploratory procedure. Results clearly demonstrate improvements in both accuracy and exploration time when using the proposed active methods compared to passive perception. Our work demonstrates that active perception has the potential to enable robots to perform robust autonomous tactile exploration in natural environments.

*Keywords:* Active tactile sensing, Bayesian perception, sensorimotor control, tactile exploration

---

**1. Introduction**

Humans purposefully move their hands and fingers to enhance the perceptual characteristics of objects being touched, which is known as active exploration [1, 2, 3]. Different exploratory procedures (EPs) are performed according to the type of information that is desired – for instance, pressure, contour following and sliding are used for extracting hardness, shape and texture [4, 5]. Motivated by this, recent advances in tactile sensing technology have improved the capability of robots to interact with their surrounding environment. In particular, robots equipped with biomimetic fingertip sensors are able to detect, explore and manipulate objects [6, 7]. However, despite these advances in tactile sensing technology, robust computational methods for real-time active control of biomimetic sensors during an autonomous exploratory procedure have not been developed.

This paper presents a novel and robust Bayesian approach for actively controlling a biomimetic fingertip during autonomous exploration of an unknown object. We consider a task of actively exploring object contours with two types of movement: 1) local repositioning to improve perception (fingertip position normal to contour), and 2) movements to accomplish the exploration task (edge orientation to move tangentially along the contour). We utilise a computational method for estimation of position and edge orientation based on Bayesian optimal decision making that reduces the uncertainty of the measurements from the tactile sensor. This method improves tactile perception by accumulating

---

\*Corresponding author

16 evidence from the object being touched while moving the sensor to a good location for perception [8, 9, 10, 11]. Here  
17 we have designed this active perception method to achieve real-time control during the discrimination of a very large  
18 dataset of perceptual classes with a tactile robot. The theoretical novelty of the proposed method is that a successful  
19 autonomous exploration strategy emerges from a relatively simple sensor-centric control.

20 In this work we define two types of sensorimotor control strategy motivated by how human decision making  
21 can be affected by prior knowledge and current expectations, according to the weight and reliability of each source  
22 of information [12, 13]. Inspired by this, we extend our methods for active exploration investigated in [14] with  
23 two sensorimotor control strategies that combine current sensory information with prior or predicted information  
24 to analyse their benefits on the exploration performance. The first sensorimotor control strategy called ‘weighted  
25 prior strategy’ takes the prior as the posterior from the previous exploration step combined with a flat prior; the  
26 second sensorimotor control strategy called ‘weighted posterior strategy’ combines instead the posterior during active  
27 perception with predicted observations. Accordingly, a forward model is developed to predict the observations by  
28 modifying the likelihoods from the active perception method. The benefits of these sensorimotor control strategies are  
29 observed in improvements to both the accuracy and speed of exploration.

30 To validate our autonomous active exploration methods, we choose a contour following exploratory procedure  
31 inspired by how humans use touch to extract the shape of an unknown object. Our methods are first validated  
32 in a simulated environment using real data from a tactile fingertip, and then secondly in a real environment on a  
33 Cartesian robot to extract various shapes in real-time. These simulated and real-time validations demonstrate the  
34 benefits of active over passive perception to successfully accomplish an autonomous exploration task using tactile  
35 sensing. Furthermore, the implementation of the proposed sensorimotor control strategies indicates how the weight  
36 and reliability of the information improve the perceptual accuracy and speed during the exploration task. The findings  
37 of this investigation provide new robust and accurate computational methods to exploit the advances and integration  
38 of tactile sensing technology in robotics.

39 The remainder of this article is organised in four sections. First, a literature review on tactile data processing,  
40 edge detection and tracking is presented. Second, the equipment, data collection and methods used for this study are  
41 described. Next, the results from simulations and robotic experiments are presented. Finally, the article provides a  
42 discussion of the findings, limitations and future research.

## 43 **2. Related work**

44 Artificial tactile sensors have been utilised in robots for many decades, enabling sensorised robots to interact  
45 physically with their surrounding environment. Planar tactile sensor technology has been widely used in robotic arms,  
46 hands and grippers. The geometry of this sensor technology means that measurements are gathered as a data matrix,  
47 which is commonly analysed with image processing algorithms [15, 16]. However, these imaging methods are not the  
48 most appropriate for biomimetic fingertip sensors, which given their rounded shape, small size and limited number of  
49 taxels cannot be treated as tactile images. Biomimetic sensor technology inspired by human fingertips is more suitable  
50 for enabling humanoid robots to manipulate, perceive and interact with objects in their environment [17]. A detailed  
51 review on advances in technology for design and fabrication of tactile sensors, and their applications in robotics is  
52 presented in [18].

53 Methods for tactile perception with biomimetic fingertip sensors can be distinguished into two types, known as  
54 passive and active perception [2, 3]. In passive perception, the fingertip interacts with an object to obtain tactile  
55 data for classification, but this data cannot affect the motion of the fingertip; conversely, in active perception, a  
56 sensorimotor feedback loop controls the fingertip to move to a better location for perception during the decision  
57 making process [14, 11]. Previous work has shown that passive tactile perception can be non-robust in unstructured  
58 environments where the position of objects is initially unknown, whereas active perception with a suitable control policy  
59 is able to correct for initially poor contacts [10]. In consequence, active perception can give an order-of-magnitude  
60 improvement in perceptual acuity over passive methods [19].

61 In human behavioural experiments, active exploration with tactile sensing has been studied through a contour  
62 following exploratory procedure, given that this is a common exploration to extract object shape information [20, 21].  
63 In robotics, edge detection has been investigated analysing the data from tactile images [22, 23]. These methods  
64 used image processing techniques to detect the edge and its orientation from the data array. Estimation of curvature  
65 for contour following was implemented by controlling the contact force, position and orientation of planar tactile  
66 sensors [24, 25, 26]. However, these methods did not consider uncertainty in the measurements and the control  
67 was based only on information from the current tactile contact during the exploration task. A superior control  
68 framework for tactile exploration using a planar sensor array was presented in [27]. This approach was based on  
69 geometrical moments from tactile images; however, such methods apply only to planar sensors composed of large  
70 arrays of taxels, not biomimetic tactile fingertips as discussed at the beginning of this section. Some methods based on  
71 active exploration of deformable objects, deformation of rounded fingertip sensor, sliding and rolling the sensor over  
72 an object being touched were implemented with a contour following exploration task [28, 29]. Active perception for  
73 edge detection, based on sensor palpations, was investigated and validated in simulated and in real-time experiments  
74 using a probabilistic approach and a biomimetic fingertip [9, 14].

75 There are several related probabilistic methods for extracting object features with tactile fingertips. The approach  
76 used here is built on an evidence accumulation framework for optimal decision making utilising tactile sensors [30,  
77 31, 32], later extended to actively repositioning the tactile sensor during perception [8, 10, 11]. Another method for  
78 exploration of shape and extraction of local environment properties was implemented using force sensors applied to  
79 surgical robots [33]. Meanwhile, a probabilistic approach for object localisation using touch has been proposed in [34],  
80 providing good accuracy but not including active behaviour to move the sensor to better locations for perception.

81 A related formalism termed Bayesian exploration [35] has superficial similarities to that used here, but there are  
82 important differences in the active perception method. The approach in [35] concerns selecting explorative movements  
83 that maximally disambiguate potential perceptual hypotheses. Conversely, here we adopted a method that uses small  
84 corrective movements during active perception to approach a preset good location for decision making [14, 9, 11], which  
85 is more analogous to feedback control and therefore suited to a contour following task. Here, the feature identification  
86 is used to guide the exploration with simple fixed rule, so that the exploration emerges from the perception. For  
87 example, a simple strategy of moving perpendicularly to an edge, once the edge angle has been perceived, will lead to  
88 a contour-following exploration of that edge.

### 89 3. Methods

#### 90 3.1. Biomimetic fingertip sensor

91 For this work, we used a biomimetic fingertip sensor that is part of the tactile sensory system of the iCub humanoid  
 92 robot [36]. This tactile sensory system provides the iCub humanoid robot with capabilities to interact with its  
 93 environment [37]. The tactile sensor resembles a human fingertip, given its rounded shape and dimensions (14.5 mm  
 94 long by 13 mm wide; shown in Figure 1).

95 The tactile fingertip is built around a capacitive technology containing an array of twelve taxels (tactile elements)  
 96 of  $\sim 4$  mm diameter each. These taxels cover the inner core of the fingertip with a flexible printed circuit board  
 97 (PCB), with a  $\sim 2$  mm dielectric layer of silicone foam placed above the PCB. The flexible and conductive outer layer  
 98 is composed of a carbon black silicone material, which also allows deformations of the surface of fingertip sensor,  
 99 analogous to those that occur with the human fingertip. The capacitive measurements read from the taxels are  
 100 digitised locally using a capacitance-to-digital converter (CDC) placed in the PCB above the inner core of the tactile  
 101 sensor. The digital measurements from the CDC are sent to a computer through a CAN-bus to be processed. The 12  
 102 capacitance measurements obtained with a sample rate of 50 Hz are digitised with 8 bit resolution (0–255 values).

103 There is a resemblance between the technology used in the tactile sensor and the mechanical and sensory structure  
 104 of the human fingertip that allows perception of pressure, curvature and edge orientation [38]. In particular, the taxels  
 105 in the tactile sensor respond analogously to human mechanoreceptors to brief and sustained response from tactile  
 106 stimuli.

Figure 1: Biomimetic iCub fingertip sensor. (A) Arrangement of circular taxels on flexible PCB covering the inner support. (B) Outer conductive layer in a standalone fingertip. (C) Physical dimensions of the tactile sensor.

#### 107 3.2. Robot

108 A robot was constructed to provide mobility to the fingertip sensor that is composed of two different robot com-  
 109 ponents: (1) a Cartesian robot arm (YAMAHA XY-x series) with 2-DoF (degrees of freedom) in the  $x$ - and  $y$ -axes,  
 110 and (2) a Mindstorms NXT Lego robot built with 1-DoF. The NXT robot is mounted on the Cartesian robot arm in  
 111 a proper manner to generate movements in the  $x$ -,  $y$ - and  $z$ -axes (see Figure 2).

112 We mounted the tactile sensor on the robot to perform precise positioning movements in the  $x$ - and  $y$ -axes with  
 113 an accuracy of  $\sim 20$   $\mu\text{m}$ . The capabilities of the NXT robot do not allow very precise movements, but these are good  
 114 enough to perform upwards and downwards movements along the  $z$ -axis. Robot movements in  $x$ -,  $y$ - and  $z$ - axes  
 115 are controlled by tactile feedback that, based on pressure measurements from the fingertip sensor, allow to perform  
 116 a tactile exploration task. Figure 2 shows the fingertip sensor mounted on the robot platform. This configuration of  
 117 the robot and the degrees of freedom do not allow rotations around the  $z$ -axis of the tactile sensor. Therefore, the  
 118 fingertip sensor keeps the same orientation during all experiments.

Figure 2: (A) Different shaped and sized objects used for active Bayesian perception applied to sensorimotor control. Two of these objects have diameters of 2 cm, 4 cm, while the third object with irregular shape has various radii of curvature. All the objects have a height of 1 cm. (B) Biomimetic fingertip sensor in contact with the edge of an object at one angle and position. (C) Tactile sensor mounted on a Cartesian robot allowing mobility in  $x$ -,  $y$ - and  $z$ - axes. (D) Mechanism of the NXT robot built to perform upwards and downwards movements along the  $z$ -axis with the fingertip sensor.

119 A tactile exploration based on taps was chosen for two main reasons. First, to reduce damage to the sensor because,  
 120 in contrast, a sliding motion could deteriorate the outer conductive layer after repeating the experiments several times.  
 121 Second, to utilise tactile exploration movement through repetitive palpations, useful for robotic system that are not  
 122 able to slide their sensors. Even though tactile fingertips are different in form to rats' whiskers, a palpating exploratory  
 123 procedure with a fingertip is analogous to the whisking movements that rats use to explore their environment. Humans  
 124 typically slide their fingertips during exploration of shape; however, in situations where there is an expectation that  
 125 damage may occur or for inspection of delicate objects (e.g. medical diagnosis), we can also perform a palpating  
 126 exploratory procedure.

Figure 3: Data collection procedure from an edge stimulus of a plastic object. The fingertip sensor collects data based on taps along the  $z$ -axis and displacement movements along  $x$ - and  $y$ -axes. The data are collected at 5 deg steps with taps along 18 mm at 0.2 mm steps perpendicular to the edge. For visualisation, we show only three examples of data collection with the fingertip sensor. In total we collected data from 72 angles and 18 mm positions each.

### 127 3.3. Data collection

128 We collected two distinct sets of tactile data for training and offline validation, exploring a single flat circular object  
 129 in a systematic and well-controlled procedure. The object was rigidly attached to the table to prevent slippage. Data  
 130 were collected by tapping against the object over different locations in the  $x$ - $y$  plane sampled in polar coordinates.  
 131 That is, given a fixed orientation angle  $w$  the object is tapped along a line radially extending from the inside of the  
 132 object (with full contact), passing over the edge (with partial contact), and ending outside the object (with no contact)  
 133 (Figure 3). Along this line, taps were performed in 0.2 mm steps over a distance of 18 mm, generating a total of 90  
 134 taps for each edge orientation. The orientation angle was changed in steps of 5 deg yielding 72 direction measurements  
 135 for a full 360 deg coverage. A single tap had a duration of 2 sec, yielding a dataset of  $12 \times 100$  pressure measurements  
 136 from the fingertip sensor (sampling frequency 50 Hz and 12 taxels). Figure 4 shows an example of the pressure signals  
 137 obtained by a single tap at full contact on the object, over the edge and outside the object.

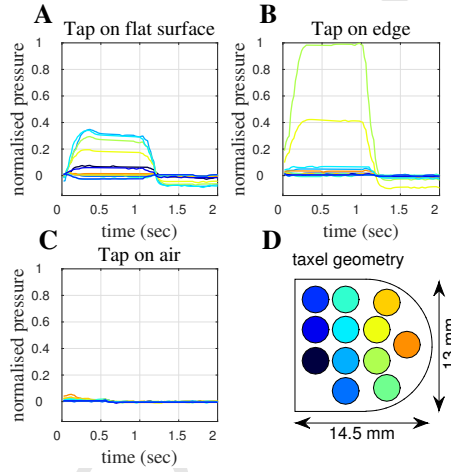

Figure 4: Tactile data at flat surface, edge and air for the fingertip sensor tapping with an angle orientation of 0 deg. (A) Tap on flat surface, where the pressure is spread to most of the taxels. (B) Tap on edge where the pressure is concentrated in a small number of taxels. (C) Tap on air, where the sensor is not in contact with the stimulus. (D) Coloured taxels layout that allows to visualise which parts of the fingertip sensor are activated for data collection at flat surface, edge and air regions.

138 Figure 5 shows examples of the normalised tactile data collected with the fingertip sensor. The pressure of the  
 139 taxels in contact with the object gradually changes along the trajectory of data collection. These variations in the  
 140 pressure are related to the orientation and positioning of the fingertip with respect to the object. Hence, from the  
 141 tactile data we are able to perceive both the angle and position of the fingertip sensor relative to the edge of the object.  
 142 Note also the present of noise — for example, the peaks just outside the object are from mechanical jerking of gears  
 143 in the robot.

144 We built position classes using groups of 5 taps per class, from the 90 taps performed for each edge orientation, and  
 145 were each group represents a position class. Then, we obtained a total of 18 position classes of 1 mm span each. These  
 146 were used to construct the classifier based on histograms [30] (Section 3.4), and moreover gave classes representing  
 147 a span of locations rather than a single position. In total, we formed a large dataset composed of  $72 \text{ angles} \times 18$   
 148  $\text{positions} = 1296$  perceptual classes. As mentioned earlier, the complete process was repeated twice to collect one  
 149 dataset for testing and one for training, with differences between these sets being characteristic of the accuracy and  
 150 repeatability of the robot.

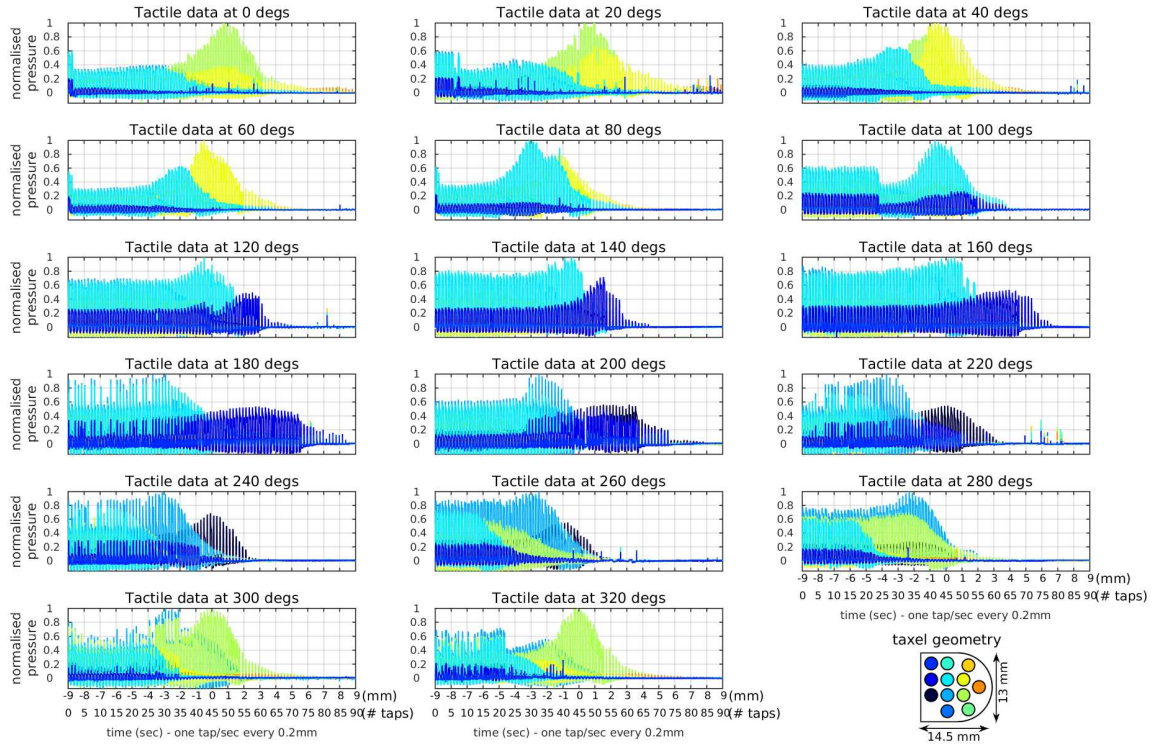

Figure 5: Tactile data collected using the method described in Section 3.3. The data collection was at 5 deg steps around a plastic object with displacement steps of 0.2mm perpendicular to the edge of the object. This was repeated 72 times covering the 360 deg of a circle. For each angle step, we took 90 contacts each within 2 seconds of data (100 samples per taxel) across the 18 mm range of positions, taking  $72 \times 90 = 6480$  contacts. The colouring of the figures denote the distinct taxels. For visualisation, here we show only 17 figures (of the 72) with data collected every 20 deg. All data within each figure are shown, but only the envelopes of the peak taxel readings are visible because of the density of contacts displayed.

### 151 3.4. Active Bayesian perception

152 Perception can be considered as either active for situations where sensory data affects the control of the sensor,  
 153 or passive when the sensory data does not affect the motion of the sensor relative to the stimulus [1, 2]. The ability  
 154 to control sensor movements using active perception based on previous sensory data, for example to explore areas of  
 155 apparent interest, gives an improvement to the perceptual performance, such as the decision speed and perceptual  
 156 accuracy.

157 Our active exploration framework is based on methods for active Bayesian perception, which have been validated  
 158 with various stimuli such as textures and shapes using the biomimetic iCub fingertip [9, 11]. These validations have  
 159 shown the versatility of these methods over a range of tactile robotic applications. The methods implement Bayes'  
 160 rule through a technique of sequential analysis [39], which recursively updates the posteriors with likelihoods obtained  
 161 from a measurement model of the tactile data until reaching a decision threshold.

162 Here, we applied active exploration to follow the unknown contour of various object shapes with a tactile fingertip  
 163 sensor. The sensor performs active repositioning movements to make better perceptual decisions about its location  
 164 and orientation (angle) relative to edge being followed. Once a decision is made, the sensor uses this information to  
 165 move along the contour, so that it may continue the exploration and thus extract the complete contour of the object.  
 166 Therefore, we use active perception for two reasons: 1) to improve classification performance by moving the fingertip to  
 167 good positions for angle perception; and 2) to provide feedback into a sensorimotor architecture to control movements

$b$	bin index	$w_i$	angle class	$w_{\text{dec}}$	angle decision
$N_{\text{bins}}$	number of bins	$z_t$	contact at time $t$	$x_{\text{loc}}$	position decision
$N_{\text{samples}}$	number of samples	$z_{1:t}$	contact history at time $t$	$x_{\text{fix}}$	target position
$N_{\text{taxels}}$	number of taxels	$P(c_n)$	uniform prior	$\pi$	movement policy
$N_{\text{loc}}$	number of position classes	$P(z_t c_n)$	location likelihood	$P_{\text{flat}}(c_n)$	uniform prior
$N_{\text{id}}$	number of angle classes	$P(z_t z_{1:t-1})$	marginal probability	$P_{\text{fwd}}(c_n \tilde{z}_T)$	forward model
$h_{kn}(b)$	sample histogram	$P(x_l z_{1:t})$	position belief	$P_{\text{prior}}(c_n z_0)$	weighted prior
$c_n$	location class	$P(w_i z_{1:t})$	angle belief	$P_{\text{posterior}}(c_n z_t)$	weighted posterior
$x_l$	position class	$\theta_{\text{dec}}$	belief threshold	decision time	$T$

Table 1: Terms and definitions

168 of the tactile sensor during the exploration task. Overall, the active Bayesian perception method consists of five layers,  
169 which are described in the following paragraphs.

#### 170 3.4.1. Sensory layer

171 The first part of the algorithm is the acquisition of tactile measurements. In this process a dataset composed  
172 of  $12 \times 100$  pressure measurements is collected by the fingertip sensor with sampling frequency of 50 Hz. The data  
173 collection is based on taps (palpations).

#### 174 3.4.2. Perception layer

175 Active perception is implemented as an estimation of contact location and orientation, in which active control of  
176 location aids identification of edge orientation. Position is thus treated as ‘location’ and the angle as ‘identity’, so that  
177 procedure may be thought of as simultaneous localisation and identification (SOLID) [8]. The classification is over  
178  $N_{\text{loc}}$  position classes  $x_l$  and  $N_{\text{id}}$  angle classes  $w_i$ , with a total of  $N = N_{\text{loc}}N_{\text{id}}$  ‘position-angle’ classes  $c_n = (x_l, w_i)$ .  
179 The  $t$ th tactile contact is represented by  $z_t$  and  $z_{1:t-1}$  the tactile contact history.

*Measurement model and Likelihood estimation:* From each tap ( $z_t$ ) we obtain a (2 second) time series with  $N_{\text{samples}} = 100$  samples of digitised pressure values from each of the  $N_{\text{taxels}} = 12$  taxels. The measurement model is constructed off-line from these sensor values using a nonparametric (histogram) estimation approach commonly used for statistical hypothesis testing. The measurement model is obtained from the frequency of (binned) sensor readings in the training data for each class

$$P_k(b|c_n) = \frac{h_{kn}(b)}{\sum_{b=1}^{N_{\text{bins}}} h_{kn}(b)}, \quad (1)$$

180 where  $h_{kn}(b)$  is the sample count in bin  $b$  for taxel  $k$  over all training data in class  $c_n$ . The histograms were uniformly  
181 constructed by binning the sensor values into  $N_{\text{bins}} = 100$  intervals. Then, for a test tactile contact  $z$ , the measurement  
182 model is built from the mean log likelihood over all samples, also taking into account the contribution from all taxels,

$$\log P(z|c_n) = \sum_{k=1}^{N_{\text{taxels}}} \sum_{j=1}^{N_{\text{samples}}} \frac{\log P_k(s_k(j)|c_n)}{N_{\text{samples}}N_{\text{taxels}}}, \quad (2)$$

183 where  $s_k(j)$  is the sample  $j$  in taxel  $k$ . The model treats all samples as independent and identically distributed for each  
184 tap and taxel. Although the independence assumption may be violated in practise, it gives a good first approximation

185 for constructing a simple likelihood model, with the caveat that results could be improved by utilising statistical  
 186 dependence of the data. Technically, this measurement model becomes ill-defined if any histogram bin is empty, which  
 187 is easily fixed by regularising the bin counts with a small additive constant [8].

188 *Priors:* We assume uniformly distributed priors for all perceptual classes  $P(c_n) = P(c_n|z_0) = 1/N$ . This defines  
 189 the posteriors at time  $t = 0$ , which will be recursively updated with the likelihoods from each tap performed by the  
 190 sensor.

191 *Bayesian update:* For updating the posterior probabilities  $P(c_n|z_{1:t})$ , we use a recursive implementation of Bayes'  
 192 rule over all  $N$  perceptual classes  $c_n$  with the likelihoods  $P(z_t|c_n)$  of the measured tap  $z_t$ . The prior takes the value  
 193 of the posterior at tap  $t - 1$  resulting in an update,

$$P(c_n|z_{1:t}) = \frac{P(z_t|c_n)P(c_n|z_{1:t-1})}{P(z_t|z_{1:t-1})}. \quad (3)$$

194 In order to give properly normalised values, the marginal probabilities are conditioned on the previous tap and  
 195 calculated from the sum

$$P(z_t|z_{1:t-1}) = \sum_{n=1}^N P(z_t|c_n)P(c_n|z_{1:t-1}). \quad (4)$$

196 *Marginal angle and position posteriors:* Each class  $c_n$  corresponds to an  $(x_l, w_i)$  pair where  $x_l$  and  $w_i$  are the  
 197 position and angle for each perceptual class respectively. The posteriors are the joint distributions over these joint  
 198 classes, then the beliefs over individual angle and position perceptual classes are given by the marginal posteriors

$$P(x_l|z_{1:t}) = \sum_{i=1}^{N_{\text{id}}} P(x_l, w_i|z_{1:t}), \quad (5)$$

$$P(w_i|z_{1:t}) = \sum_{l=1}^{N_{\text{loc}}} P(x_l, w_i|z_{1:t}), \quad (6)$$

199 with the position beliefs summed over all angle classes and the angle beliefs summed over all position classes.

### 200 3.5. Stop rule and decision layer

201 A threshold crossing rule is used to stop accumulating evidence and make a decision about the angle and position  
 202 class. The *maximum a posteriori* (MAP) estimate is used to decide the angle and position perceptual class when the  
 203 angle belief exceeds a threshold

$$\begin{aligned} &\text{if any } P(w_i|z_{1:t}) > \theta_{\text{dec}} \\ &\text{then } w_{\text{dec}} = \arg \max_{w_i} P(w_i|z_{1:t}), \end{aligned} \quad (7)$$

204 where  $w_{\text{dec}}$  is the angle class estimated after tap  $t$ . The estimated angle  $w_{\text{dec}}$  is employed in the contour following  
 205 exploration presented in Section 4.2 to move the tactile sensor along the edge of an object. We use the angle decision  
 206 threshold  $\theta_{\text{dec}} \in [0, 1]$  to set the trade-off between decision speed and accuracy. The use of the angle class as the stopping  
 207 criterion is appropriate for our chosen task of contour following because it is the angle decision that determines the  
 208 direction of the next exploration step along the contour, as presented in Sections 4.2 and 4.3.

Figure 6: Active perception algorithm. The *sensory* layer reads the tactile measurements from the sensor. The *perception* layer is responsible for updating the evidence accumulated based on Bayes' rule. The decision-making based on the MAP estimate once the belief threshold is crossed is performed in the *decision* layer. The *active* layer permits to the sensor to be repositioned for improvement of perception. The output from the decision-making process is used by the *control* layer for enacting the corresponding action.

### 209 3.5.1. Active layer

210 In previous work, we have found that for this biomimetic fingertip sensor the perception is improved towards its  
 211 centre [8, 9]. Also, as we will see later, this is supported by our results (Section 4.1). Therefore, for active perception  
 212 we assume that there is a preset target position  $x_{\text{fix}}$  at the centre of the sensor that the active control seeks to attain  
 213 from an initially unknown fingertip location. The movement policy represented by  $\pi$  is then determined from the  
 214 current position estimation  $x_{\text{loc}}$ ,

$$x_{\text{loc}} = \arg \max_{x_l} P(x_l | z_{1:t}), \quad (8)$$

$$x \leftarrow x + \pi(x_{\text{loc}}), \quad \pi(x_{\text{loc}}) = x_{\text{fix}} - x_{\text{loc}}, \quad (9)$$

215 where  $\pi(x_{\text{loc}})$  updates the value of  $x$  which is the new position of the sensor.

216 The number of updated or repositioning movements performed by the sensor is related to the belief threshold. Low  
 217 belief thresholds are exceeded quickly, not allowing the repositioning of the sensor to a good location for perception  $x_{\text{fix}}$   
 218 to result in fast but low accuracy decisions. Conversely, high belief thresholds require a large number of repositioning  
 219 movements, because the position estimate may be incorrect, which allows a gradual repositioning of the sensor to a  
 220 good location for perception to result in accurate but slow decisions. The flowchart in Figure 6 shows the sequence of  
 221 steps required to perform our active perception algorithm.

### 222 3.5.2. Control layer

223 The decision about the location of the tactile sensor is used to calculate the next location to move the sensor along  
 224 the object contour being explored. The estimated angle  $w_{\text{dec}}$  is used to calculate the next exploratory movement of  
 225 the sensor in Cartesian coordinates:

$$\text{MOVE} = (d \cos w_{\text{dec}}, d \sin w_{\text{dec}}) \quad (10)$$

226 defined by moving a fixed distance  $d = 2\text{mm}$  (Figure 7) along the perceived angle of the edge. Once the robot moves  
 227 the fingertip sensor to the new position, the complete active Bayesian perception process is repeated.

228 The length of translation for each exploratory movement, after each angle decision, is set to a fixed value (of 2 mm).  
 229 In principle, the translation step could vary along the exploration path, but this would require forward models that  
 230 are adaptive and hence go significantly beyond the present treatment.

Figure 7: Calculation of the next position along the object contour based on the current position and perceived angle  $w_{\text{dec}}$ . After moving, the active perception process is repeated, ensuring that the fingertip follows the object contour.

### 231 3.6. Sensorimotor control strategies

232 We extend the above active perception method by combining it with two sensorimotor control strategies (Figure 8).  
 233 The strategies are based on a weighted combination of present and preceding information, where the weight param-  
 234 eterises the reliability of each source [40]. We will examine later how these strategies affect the speed and accuracy of  
 235 the exploration.

#### 236 3.6.1. Weighted prior

237 Our first sensorimotor control strategy is called ‘weighted prior strategy’, and modifies the prior used in the active  
 238 angle perception according to the perceptual decision from the previous exploratory step. Previous works [9, 14]  
 239 have used a flat prior, which is equivalent to treating each decision as independent. However, the preceding posterior  
 240 probability represents an important source of knowledge that if properly used by the forward model can improve  
 241 predictions for the next angle observation.

242 Here we consider a prior for the current perceptual decision as a weighted combination of the preceding poste-  
 243 rior with a uniform distribution. Denoting this preceding posterior by  $P_{\text{fwd}}(c_n|\tilde{z}_T)$  and the uniform distribution by  
 244  $P_{\text{flat}}(c_n) = 1/N$ , the prior is

$$P_{\text{prior}}(c_n|z_0) = \alpha P_{\text{fwd}}(c_n|\tilde{z}_T) + (1 - \alpha)P_{\text{flat}}(c_n), \quad (11)$$

245 with  $\alpha \in [0, 1]$  parameterising the importance of preceding information. Thus  $\alpha = 0$  corresponds to discarding  
 246 preceding information, so each decision is independent;  $\alpha = 1$  ensures that perceptual decisions are made only from  
 247 preceding information (since the prior is always above decision threshold).

In the above, the probability distribution  $P_{\text{fwd}}(c_n|\tilde{z}_T)$  is taken from a forward model applied to the posteriors  
 $P(c_n|\tilde{z}_T)$  from the *preceding* exploration step. For this study, we assume that the forward model is a  $\Delta = 5$  deg  
 increment (one angle class) for each exploration step, compatible with the angular resolution of the training data (see  
 Section 3.3). Hence

$$P_{\text{fwd}}(c_n|\tilde{z}_T) = P_{\text{fwd}}(x_l, w_i|\tilde{z}_T) = P(x_l, w_i + \Delta|\tilde{z}_T), \quad (12)$$

Figure 8: (A) Sensorimotor control based on a weighted prior. The posterior from active perception from the previous decision is used as a prior weighted by a confidence factor. This prior is also shifted by a parameter  $\Delta = 5$  deg. (B) Sensorimotor control strategy based on a weighted posterior. The decision making is based on the weighted combination of the posterior from active perception and predicted observations. The updated posterior is shifted by a parameter  $\Delta = 5$  deg and used for prediction of the current decision.

where  $w_i + \Delta$  are the angle observations shifted by  $\Delta$ .

The movement of the tactile sensor along the contour of the object being explored is performed by the ‘Control layer’, which uses the estimated angle class to accomplish the exploration task. Thus, the forward model is designed to affect only angle classes  $w_i$ . Position classes  $x_l$ , which are not affected by the forward model, are still locally controlled based on active repositions (equations 8 - 9). The weighted prior strategy is shown in the diagram of Figure 8a.

### 3.6.2. Weighted posterior

Another approach is to combine the posterior from the preceding exploration step with the posterior from the current exploration step, to obtain a weighted posterior that can be compared with the threshold criterion for decision termination. Technically, this is equivalent to using information from the preceding exploration step to modify the decision thresholds for the perceptual choices, but is easier to implement with the posteriors.

Thus the ‘weighted posterior’ sensorimotor control strategy uses a posterior

$$P_{\text{posterior}}(c_n|z_t) = \alpha P_{\text{fwd}}(c_n|\tilde{z}_T) + (1 - \alpha)P(c_n|z_t), \quad (13)$$

that combines the present posterior  $P(c_n|z_t)$  at tap  $t$  with the predicted posterior  $P_{\text{fwd}}(c_n|\tilde{z}_T)$ . (All notation is the same as the weighted prior strategy, above, including the same forward model (12).) The parameter  $\alpha \in [0, 1]$  again represents the importance of preceding information:  $\alpha = 0$  corresponds to discarding preceding information, and  $\alpha = 1$  ensures decisions are made only from preceding information.

The resulting posterior (13) then provides position  $P_{\text{posterior}}(x_l|z_t)$  and angle  $P_{\text{posterior}}(w_i|z_t)$  probabilities from analogous equations to (5) and (6). In consequence, the final angle decision for each exploration step is given by

$$\begin{aligned} &\text{if any } P_{\text{posterior}}(w_i|z_t) > \theta_{\text{dec}} \\ &\text{then } w_{\text{dec}} = \arg \max_{w_i} P_{\text{posterior}}(w_i|z_t). \end{aligned} \quad (14)$$

Note the active perception is also affected via the location estimate  $x_{\text{loc}} = \arg \max_{x_l} P_{\text{posterior}}(x_l|z_t)$ . The weighted posterior strategy is shown in the diagram of Figure 8b.

## 266 4. Results

### 267 4.1. Off-line validation of passive and active perception

268 *Passive angle and position perception:* First, we investigate how evidence accumulation across successive taps can  
 269 lead to successful perception, with no feedback from perception into the control of the sensor. A tapping process  
 270 without repositioning the sensor was repeated until the belief for one of the angle classes crossed a threshold, which  
 271 then triggered a decision about the angle and position where the fingertip is located. This approach is known as passive  
 272 Bayesian perception, meaning that the tactile fingertip is not able to move to another location to improve perception.  
 273 The validation was based on an off-line Monte Carlo method with 10,000 iterations per belief threshold taken over  
 274 the range  $\theta_{\text{dec}} \in [0.0, 0.05, \dots, 0.95, 0.99]$ . For each iteration of the simulation process, data was randomly sampled  
 275 with replacement from one of the 1296 (72 angle by 18 position) test classes until reaching decision threshold, using  
 276 the validation and training data described in Section 3.3. This experiment was based on the flowchart in Figure 6,  
 277 removing the modules in the red dashed-line box and considering only the inner loop.

278 Figure 9 shows the results for passive angle (top panel) and position (bottom panel) perception over 72 angle classes  
 279 with the smallest mean classification error of 3.7 deg, measured as the mean absolute difference between the perceived  
 280 and actual angle class averaged over simulation trials. The bottom of Figure 9 shows the number of taps required  
 281 to make a decision for each belief threshold. The decision time was averaged over the number of taps required for

Figure 9: Angle acuity based on a passive Bayesian perception. The top ‘ring’ figure shows the accuracy classification over 72 angles and 18 position perceptual classes. Acuity is measured by mean absolute angle error, with large and small errors shown as red and white respectively, corresponding to values presented in the colour bar. The bottom figure shows the results for position dependency averaged over the angles.

Figure 10: Angle and position acuity for active (green) and passive (red) perception, using an off-line Monte Carlo method. (A) Angle and (B) position errors are plotted against mean decision time. These errors are obtained by computing the mean absolute difference between the perceived and actual classes over all trials and for each belief threshold. One typical low decision threshold  $\theta_{\text{dec}} = 0.2$  (o) and high threshold  $\theta_{\text{dec}} = 0.9$  (+) are shown.

282 making a decision over the 10,000 iterations. We observe that the best position class for perception is at 0 mm, at the  
 283 mid-point of the considered position range and roughly at the centre of the fingertip sensor.

284 *Active angle and position perception:* Next, we examine active perception with a sensorimotor control loop that  
 285 moves the fingertip to improve perception based on tactile feedback (Figure 6). We used the training and testing  
 286 datasets collected previously (see Section 3.3).

287 Our active perception method requires a target fixation position to move to. The results in Figure 9 indicate that  
 288 the target fixation position class 0 mm provides the smallest classification error, ensuring the optimal perception. The  
 289 angle and position acuity for passive perception (red curve) and active perception (green curve) plotted against mean  
 290 decision time are shown in Figures 10A,B, measured by the mean absolute error averaged over all trials for each belief  
 291 threshold in the range  $[0.0, 0.05, \dots, 0.95, 0.99]$ . We observe the smallest angle and position errors of 12.2 deg and  
 292 0.8 mm for passive perception. In contrast, angle and position errors of 3.3 deg and 0.2 mm were obtained with active  
 293 perception, showing considerable improvement over passive perception. We observe that  $\sim 5$  taps is sufficient to obtain  
 294 angle and position errors close to the minimum, giving the best decisions using active perception.

#### 295 4.2. Off-line validation of sensorimotor architecture

296 Our sensorimotor architecture is now used to implement object shape extraction in a simulated environment using  
 297 the data analysed in the previous section. The implementation is composed of the modules shown in Figure 6. The  
 298 simulated environment is based on a circular shaped object, corresponding to the data collected from the fingertip  
 299 sensor with angle resolution of 5 deg (shown in Figure 5).

300 For the off-line validation we used active perception with a target position class 0 mm chosen according to the active  
 301 and passive perception results from Section 4.1. The circular shaped object and the results of the autonomous active  
 302 exploration with passive and active perception are shown in Figure 11. Black solid lines represent the boundaries of  
 303 the exploration, whilst the contour to be traced by the fingertip sensor is shown as a black dotted line, with each  
 304 dot representing an angle at 5 deg. The small green and red circles represent the locations explored by the fingertip  
 305 sensor for active and passive perception. Note that in this off-line task it is not possible for the exploration to fail  
 306 catastrophically, in that the sensor cannot completely lose track of the contour as it can do on the real-time task  
 307 considered in Section 4.3. Instead, we quantify the quality of the contour following exploration.

Figure 11: Traced contours with active and passive exploration (off-line validation). The black dotted line represents the contour to be traced and the black solid line represent the boundaries of the exploration. The results for passive and active perception are shown for low ( $\theta_{\text{dec}} = 0.2$ ) and high ( $\theta_{\text{dec}} = 0.9$ ) decision thresholds. The small circles represent the locations explored by fingertip sensor. Multiple circles for high decision threshold represent the multiple taps required before making a decision. In contrast, only one tap is needed for low decision threshold.

308 For passive perception with low decision threshold  $\theta_{\text{dec}} = 0.2$ , we observe that the contour following is fast but has  
 309 large angle and position errors, consistent with only small beliefs being necessary to make a decision. At high decision  
 310 threshold  $\theta_{\text{dec}} = 0.9$  the errors are decreased, but only slightly, even though the fingertip makes more taps on each  
 311 angle decision, slowing the time to trace the contour.

312 For active perception with low decision threshold  $\theta_{\text{dec}} = 0.2$ , the fingertip sensor is actively repositioned but not  
 313 able to perform enough active movements to improve perception. In contrast, active perception with high decision  
 314 threshold  $\theta_{\text{dec}} = 0.9$  clearly shows an improvement in angle and position perception, successfully accomplishing the  
 315 contour following task. Underlying these results, if the method makes a bad initial angle and position perception  
 316 (as in passive perception or active perception with low threshold), the sensor will not be able to follow the contour  
 317 of the object. Conversely, for moderately inaccurate initial perception (as in active perception with high threshold),  
 318 the accuracy of the angle and position perceived is corrected along the exploration, and the contours are successfully  
 319 traced. Thus, our approach for active perception ensures that the exploration method will achieve good performance  
 320 by correcting its perception during the task.

321 Summary results for passive and active exploration around the entire contour are shown in Figure 12, where the  
 322 position and angle acuity is evaluated by averaging over 5000 complete loops of the contour (in contrast with Figure 10,  
 323 where perceptual decisions are considered independently of contour following). For each contour, the initial location  
 324 (angle and position) were randomly drawn to prevent biasing. The belief thresholds used for this validation were set to  
 325 the range  $[0.0, 0.05, \dots, 0.95, 0.99]$ . Position and angle acuity is again measured by the mean absolute errors between  
 326 their perceived and actual values, and displayed per decision around the contour. Evidently, the mean angle and  
 327 position errors for active (green curves) perception are much improved over those for passive (red curves) perception,  
 328 consistent with the qualitative observations from Figure 11 for a single contour. We observe that the smallest angle  
 329 and position errors for active perception are  $\sim 4$  deg and  $\sim 0.2$  mm, averaged over a contour, which are considerably  
 330 improved over the values  $\sim 27$  deg and  $\sim 6$  mm for passive perception.

331 *Active perception and weighted prior:* We analysed the effects of a weighted prior applied to active perception with  
 332 the contour following task described in the previous section. The algorithmic implementation is based on the diagram  
 333 shown in Figure 8a and equations (11) and (12) for weighting and shifting the prior knowledge obtained from our  
 334 active perception method. The weighting  $\alpha$  of preceding information is considered over values  $[0.0, 0.05, \dots, 0.95,$   
 335  $0.99]$ . Results are obtained by averaging over the individual decisions comprising the exploration around a contour  
 336 for each weighting value. Again, the belief thresholds were taken over the range  $[0.0, 0.05, \dots, 0.95, 0.99]$ , averaging

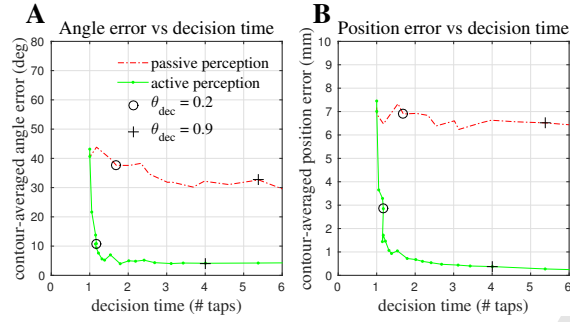

Figure 12: Contour-averaged angle and position acuity while performing a simulated contour following task using a circle shape constructed with real data. (A) Angle and (B) position errors for passive (red curves) and active (green curves) perception are plotted against mean decision time. All results are averaged over 5000 contour exploration loops, contrasting with Figure 10 where results are over individual decisions. One typical low decision threshold  $\theta_{\text{dec}} = 0.2$  ( $\circ$ ) and high threshold  $\theta_{\text{dec}} = 0.9$  ( $+$ ) are shown

337 results over 5000 contours with randomly chosen initial conditions.

338 Results are considered over the range of the prior weighting  $\alpha \in [0, 1]$  (Figure 13). For  $\alpha = 0$  (lightest curve),  
 339 the control strategy corresponds to the flat prior case considered earlier, and accordingly is identical to the results  
 340 in the previous section (Figure 12). For  $\alpha = 1$  (darkest curve), the prior corresponds to the complete posterior from  
 341 the preceding time step, thereby crossing the threshold at time zero after every step of the exploration after the first  
 342 decision, and not being able to use new data after the first decision.

343 Overall, the speed and accuracy for angle and position exploration do not depend greatly on values of  $\alpha \neq 0$ , with  
 344 a slight performance improvement in changing from zero (flat prior) to non-zero values of  $\alpha$ . Curiously, there is a  
 345 minimum in the error-decision time curve for angle perception (Figure 13A), rather than monotonically decreasing as  
 346 is usually the case; we interpret this as a simulation artefact due to having an exactly known forward model, so that  
 347 quick estimates will maintain good decisions. The smallest angle and position errors are 2.6 deg and 0.15 mm for a  
 348 decision time just above 1 tap and weighting  $\alpha$  anywhere from 0.1-1. These results are improved over the performance  
 349  $\sim 4$  deg and  $\sim 0.2$ mm when information from preceding decisions is not used.

350 *Active perception and weighted posterior:* The application of a weighted posterior to active perception is now exam-  
 351 ined with the contour following task used in the previous section on the weighted prior strategy. The implementation  
 352 is based on the diagram shown in Figure 8b and equations (13 - 14); all other aspects of the analysis are unchanged  
 353 from those above.

Figure 13: Contour-averaged angle and position acuity using sensorimotor active control with a weighted prior strategy. Mean absolute angle (A) and position (B) errors are plotted against decision time, with the weighting of the prior ( $\alpha$ ) denoted by a colour in the heat-map range from  $[0, 1]$ . Note that the results in Figure 12C,D correspond to the  $\alpha = 0$  (flat prior) case here.

Figure 14: Contour-averaged angle and position acuity using sensorimotor active control with a weighted posterior strategy. Mean absolute angle (A) and position (B) errors are plotted against decision time, with the weighting of the posterior ( $\alpha$ ) denoted by a colour in the heat-map range from  $[0, 1]$ . The speed and accuracy of angle and position perception is improved as alpha increases until just less than 1.

Results are considered over the range of the posterior weighting  $\alpha \in [0, 1]$  (Figure 14). For  $\alpha = 0$  (lightest curve), the control strategy corresponds to the flat prior case considered earlier (Figure 12). For  $\alpha = 1$  (darkest curve), the strategy corresponds to using the posterior from the preceding decision, which thus crosses the threshold on the initial contact. Figures 14A,B show an improvement in angle and position perception as the weighting increases for  $\alpha > 0$ , but then deteriorates again as  $\alpha$  reaches 1. Both the speed and accuracy not only show a clear dependency on  $\alpha$  but also an improvement over the original strategy considered earlier ( $\alpha = 0$ ). The smallest angle and position errors are 1.4 deg and 0.04 mm at a reaction time of 2-3 taps for a weighting  $\alpha$  just below 1. These results are improved over those of the weighted prior strategy and the original perception process when information from preceding decisions is not used.

For sub-optimal values of the weighting  $\alpha$ , the results are more varied between the two control strategies, with the weighted prior strategy sometimes better than the weighted posterior strategy depending on  $\alpha$  and the decision time. Meanwhile, for the best value of  $\alpha$  (just below unity), the weighted posterior strategy shows a superior performance in speed and accuracy over the weighted prior strategy, and overall is the best sensorimotor control strategy.

#### 4.3. Real-world validation

*Sensorimotor architecture and active perception:* We implemented a real-time contour following around a circular shaped object using our method for autonomous exploration (see Sec. 3.2 for details of the robot). In this task, the fingertip sensor performs one tap, evaluating if the belief for the current location exceeds the belief threshold. If the belief threshold is exceeded, then a decision is made, allowing the fingertip to move along the edge of the object to continue with the exploration task. If more evidence is required to make a decision, the tactile sensor is actively moved to a better position for perception, accumulating evidence until the belief threshold is exceeded.

Figure 15: Traced contours of a circular object with active and passive exploration (real-time validation). Passive perception with low ( $\theta_{\text{dec}} = 0.2$ ) and high thresholds ( $\theta_{\text{dec}} = 0.9$ ) did not accomplish the exploration task. This behaviour was similar for active perception with low threshold. Conversely, active perception with high threshold was able to successfully trace the contour of the object.

374 We first assess whether successful contour following is achieved for either passive or active exploration with low  
 375 or high decision thresholds (Figure 15). The tactile fingertip was not able to follow the contour of the object for  
 376 either passive perception or active perception with a low decision threshold, since both of these cases did not permit  
 377 movements to superior positions for edge classification. For active perception with high decision threshold, the fingertip  
 378 sensor successfully accomplishes the contour following task, making a complete path around the object. Note that  
 379 locations where active perception moved the tactile fingertip to improve angle perception are visible with multiple  
 380 contacts (green circles). These are mainly visible on the left-side region of the object, and were evidently necessary  
 381 for successful tracing of the complete contour.

382 We also validate the active exploration with various other shapes. Figure 16A shows three plastic objects used for  
 383 the exploration task: two circles of 2 cm and 4 cm diameters and an irregular object (sellotape holder) with different  
 384 curvatures. The height for all the objects is of 1 cm. These objects provide a good test scenario for exploration based  
 385 on the wide range of angles and radii of curvature. The decision threshold  $\theta_{dec} = 0.85$  is set at a high value to give  
 386 a few taps per decision before making the next exploration movement. We observe in Figure 16B that the contour of  
 387 the three test objects is successfully traced, which validates the robustness of our methods.

Figure 16: Contour following task using active exploration and tactile sensing. (A) Circles with 2 cm, 4 cm diameter and an asymmetric object (sellotape holder) used for real-time contour following. (B) Contours traced as result of active perception with high decision threshold.

388 *Sensorimotor control strategies:* We repeated the preceding real-time contour following procedure to validate our  
 389 two proposed sensorimotor control strategies: the weighted prior and weighted posterior strategies. For these exper-  
 390 iments, the weighting factor  $\alpha$  between the appropriate probabilities (see Section 3.6) was set to 0.0, 0.7 and 1.0, to  
 391 observe their different effects on the perception during exploration.

392 The results for angle and position perceptual accuracy against reaction time for both strategies are shown in  
 393 Figure 17. For  $\alpha = 0$ , the angle and position performance is similar, as expected because the two control strategies  
 394 then coincide with the unmodified case considered above. The angle performance is also worse than at non-zero  $\alpha$ ,  
 395 as consistent with the off-line validation results found earlier in the paper. For  $\alpha > 0$ , both sensorimotor control  
 396 strategies show a similar best angle accuracy with a minimum error of 1.98 deg. However, the performance of the  
 397 two sensorimotor control strategies differs in the position errors, where the weighted posterior strategy has superior  
 398 performance to the weighted prior strategy, and also in the reaction times where the weighted posterior strategy is  
 399 apparently slower than the weighted prior strategy.

400 We interpret the observed change in trend of the curves in Figure 17 as related to the effects of the initial prior

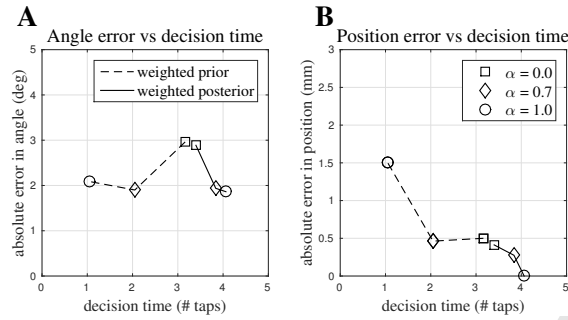

Figure 17: Comparison of weighted prior and weighted posterior strategies over a contour following task in real-time mode. The confidence factor ( $\alpha$ ) is set to values 0.0, 0.7 and 1.0 to compare their effects during the exploration task. (A) Angle and (B) position errors against decision time for the  $\alpha$  values.

401 and belief threshold on the accuracy and decision time. For the weighted prior strategy, the larger the prior the less  
 402 the time required to exceed the belief threshold to make a decision; conversely, the weighted posterior strategy takes  
 403 more time to make a decision for large belief thresholds given that its initial prior is uniformly distributed. Overall, we  
 404 observe how the real-time exploration of an unknown object using these sensorimotor control strategies has benefited  
 405 by improvements in accuracy and speed, compared to the results achieved with no effect from preceding observations  
 406 during the exploration task.

## 407 5. Discussion

408 This study presented an investigation of autonomous active exploration using sensorimotor control of a biomimetic  
 409 tactile fingertip. This research demonstrated first how active movements of a tactile fingertip improve the classification  
 410 accuracy over passive perception. Secondly, it also demonstrated how the use of sensorimotor control strategies based  
 411 on the combination of information from past and future states with active perception provide benefits for the speed  
 412 and accuracy of perception, hence improving the performance of the autonomous exploration of unknown objects.

413 We found that active Bayesian perception can achieve accurate classification in edge orientation angle and po-  
 414 sition by utilising active movements to reposition the tactile sensor to a better location for perception [9, 32]. This  
 415 demonstrates its superiority over passive perception, where the sensor is not actively controlled. For biomimetic tactile  
 416 fingertips, this approach makes possible edge detection with fine angular resolution, providing an alternative to image  
 417 processing techniques [15, 16] that work only for planar sensors with high taxel densities (unlike common biomimetic  
 418 sensors). Moreover, in principle, our method is not only applicable to edge detection but other stimuli such as texture  
 419 and curvature [8, 10]. We validated our methods with a tactile data set of 72 angle and 18 position classes, forming a  
 420 very large set of 1296 perceptual classes. The benefits of active perception were observed in the  $\sim 3.3$  deg and  $\sim 0.2$  mm  
 421 angle and position errors achieved, compared with  $\sim 12.2$  deg and  $\sim 0.8$  mm for passive perception. It is interesting  
 422 that our results are superior in accuracy for angle discrimination to those found in both sighted and blind humans  
 423 under psychophysical studies using active touch [20, 21].

424 A new sensorimotor architecture controlled by tactile feedback was developed to provide mobility to the fingertip  
 425 sensor and validate our active perception method. During an exploration task, the tactile sensor reacts (reflex move-  
 426 ment) whenever a contact is detected to move away as a protection behaviour, and then perceive and make a decision  
 427 using active Bayesian perception, performing either a local repositioning movement for accumulating evidence or an

exploratory movement to next state of the exploration task. We used taps (palpations) for the exploration task for two reasons: 1) inspiration from humans in situations when they prefer to palpate rather than slide over a surface given the possibility of hurting oneself or damaging the explored object (as in medical inspection), and 2) to reduce damage to the artificial tactile sensor over multiple repetitions of the experiments.

Our tactile perception method enables a biomimetic fingertip sensor to accurately perceive edge orientation and utilise this information to perform higher level tasks, e.g. tactile exploration. This process bears analogy with studies from neuroscience that suggest that first-order tactile neurons in human fingertips are responsible for extracting geometric features (for instance, edge-orientation detection) and signal them via both temporal and rate codes [41]. Moreover, to extract object shape, humans rely on a contour following exploratory procedure using their fingers [4, 42]. This is considered an active rather than a passive exploration, meaning that the fingers need to be controlled to provide better perception.

We validated our methods for autonomous active exploration with a contour following task, and repeated this experiment with various shapes to cover a large set of angles and radii of curvature to demonstrate robustness (Figure 16). The successful shape extraction in both off-line and real-time experiments shown in Figures 11 and 15 reinforces the benefits of active over passive perception. In addition, not only is active perception necessary for task completion, but also the perception needs to be highly reliable, which is attained only for high decision thresholds. Setting a high decision threshold also increases the decision time, which slows the exploration. This is reasonable, given that humans not only explore actively but also employ the appropriate timing until sufficient belief about the object being explored is reached [43].

Finally, we investigated the effects on exploration accuracy and time of modifying the active exploration with sensorimotor control strategies that combine present sensory information with preceding or predicted information. First, we found that using a weighted prior as input to active perception produced a reduction in the angle and position errors, whilst improving the exploration time. This finding is coherent bearing in mind that less evidence would then be required to achieve faster decisions, since evidence is already present in the prior. Second, for the weighted posterior strategy, combining the output of the active perception method with predicted observations also gave improved performance accuracy and exploration. These sensorimotor control strategies show that the combination of information sources improves the performance of the autonomous active exploration. They also demonstrate that this improvement depends on the weight assigned to each information source, which corresponds to the theory of motor control in [40] and human studies of the decision making process during a discrimination task [12].

Our proposed approach for autonomous tactile exploration has been validated in two dimensions; however, we expect the methods are scalable to explore edges in three dimensions or potentially other types of path. Applying the method to more dimensions and other realistic scenarios would require a robot with more degrees of freedom, such as rotating the fingertip sensor around any axis and controlling better the height of the sensor. The systematical data collection would also need to be extended to the added degrees of freedom.

Overall, we presented a study of autonomous active exploration with sensorimotor control strategies using a biomimetic fingertip sensor. This work shows how reliability is important for tactile sensing and how this can be achieved with active perception. In robotics, this aspect of active perception can be combined with control to result in improved performance for autonomous exploration. Overall, we have demonstrated that our methods give robust autonomous tactile exploration of unknown objects, which can take advantage of the many advances taking place in

467 robotic sensing technology to extend to natural, complex and unstructured environments.

## 468 6. Conclusion

469 In this work we presented a novel and robust method, composed of active Bayesian perception and sensorimotor  
 470 control strategies, for autonomous exploration of unknown object shapes using tactile sensing. Our method not  
 471 only allowed a fingertip sensor to perceive and make decisions about where to move next to reduce uncertainty,  
 472 but also it permitted to improve the accuracy and speed of an exploration task. Our method was validated in off-  
 473 line and real-time modes, successfully exploring and extracting the contours of various object shapes. Undoubtedly,  
 474 development of robust tactile perception methods, like the one presented in this work, are essential to achieve intelligent  
 475 and autonomous robots that safely interact, make decisions and behave accordingly to what they perceive from its  
 476 surrounding environment.

## 477 7. Acknowledgement
