7. High speed videos and flame speed of the luminous oak dust flame propagation for $<63\mu\text{m}$ dusts.

8. High speed videos for coarse oak particle size dusts.

9. Ignition delay for coarse particles

10. Flame propagation mechanism for coarse particles

11. Conclusions

Pulverised biomass is a significant source of renewable electricity and hence plays an important role in carbon reduction strategies. In the UK pulverized woody biomass burning in existing coal fired power stations generated 5.7% of electricity in 2014.

This biomass is burned either co-fired with coal or increasingly as 100% pulverised biomass. The biomass particle size fed to burners is relatively coarse as pelletised wood is feed to the coal millers which break the pellets into the size of the original wood from which the pellets are formed, which is not very fine. Also any fines in the storage and transport of the pellets are removed prior to transfer of the pellets to the burners (this can be up to 10% of the total pellet mass).

Little of the pulverised wood is $<63\mu\text{m}$ and most in the 63 to $1000\mu\text{m}$ size range. There is little information on how these relatively coarse biomass particles propagate flames in boilers.

Also, their associated dust explosion hazards is not known.

This work presents high speed videos of flame propagation in coarse particle biomass dust clouds as a means of deducing the mechanism of flame propagation.

In the UK there is 3 GW of bioenergy plants generating renewable electricity (2 GW at Drax, Yorkshire).

4 GW of bioenergy plant is in planning and in addition Drax is planning to upgrade to 4 GW.

Biomass stores at Drax are the largest material stores in the world and are two orders of magnitude bigger than any dust explosion test has been carried out.

It is Government policy to phase out coal through a carbon tax only on coal and the industry is fighting to keep the power stations in business by converting to biomass.

The fuels are pellets (mainly from wood at Drax), miscanthus, straw, poultry litter, food recycling, paper mill residues, waste construction wood and agricultural residues. The dominant biomass is wood, sourced from anywhere in the world that can provide it sustainably. Little data on explosion risks exist!

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

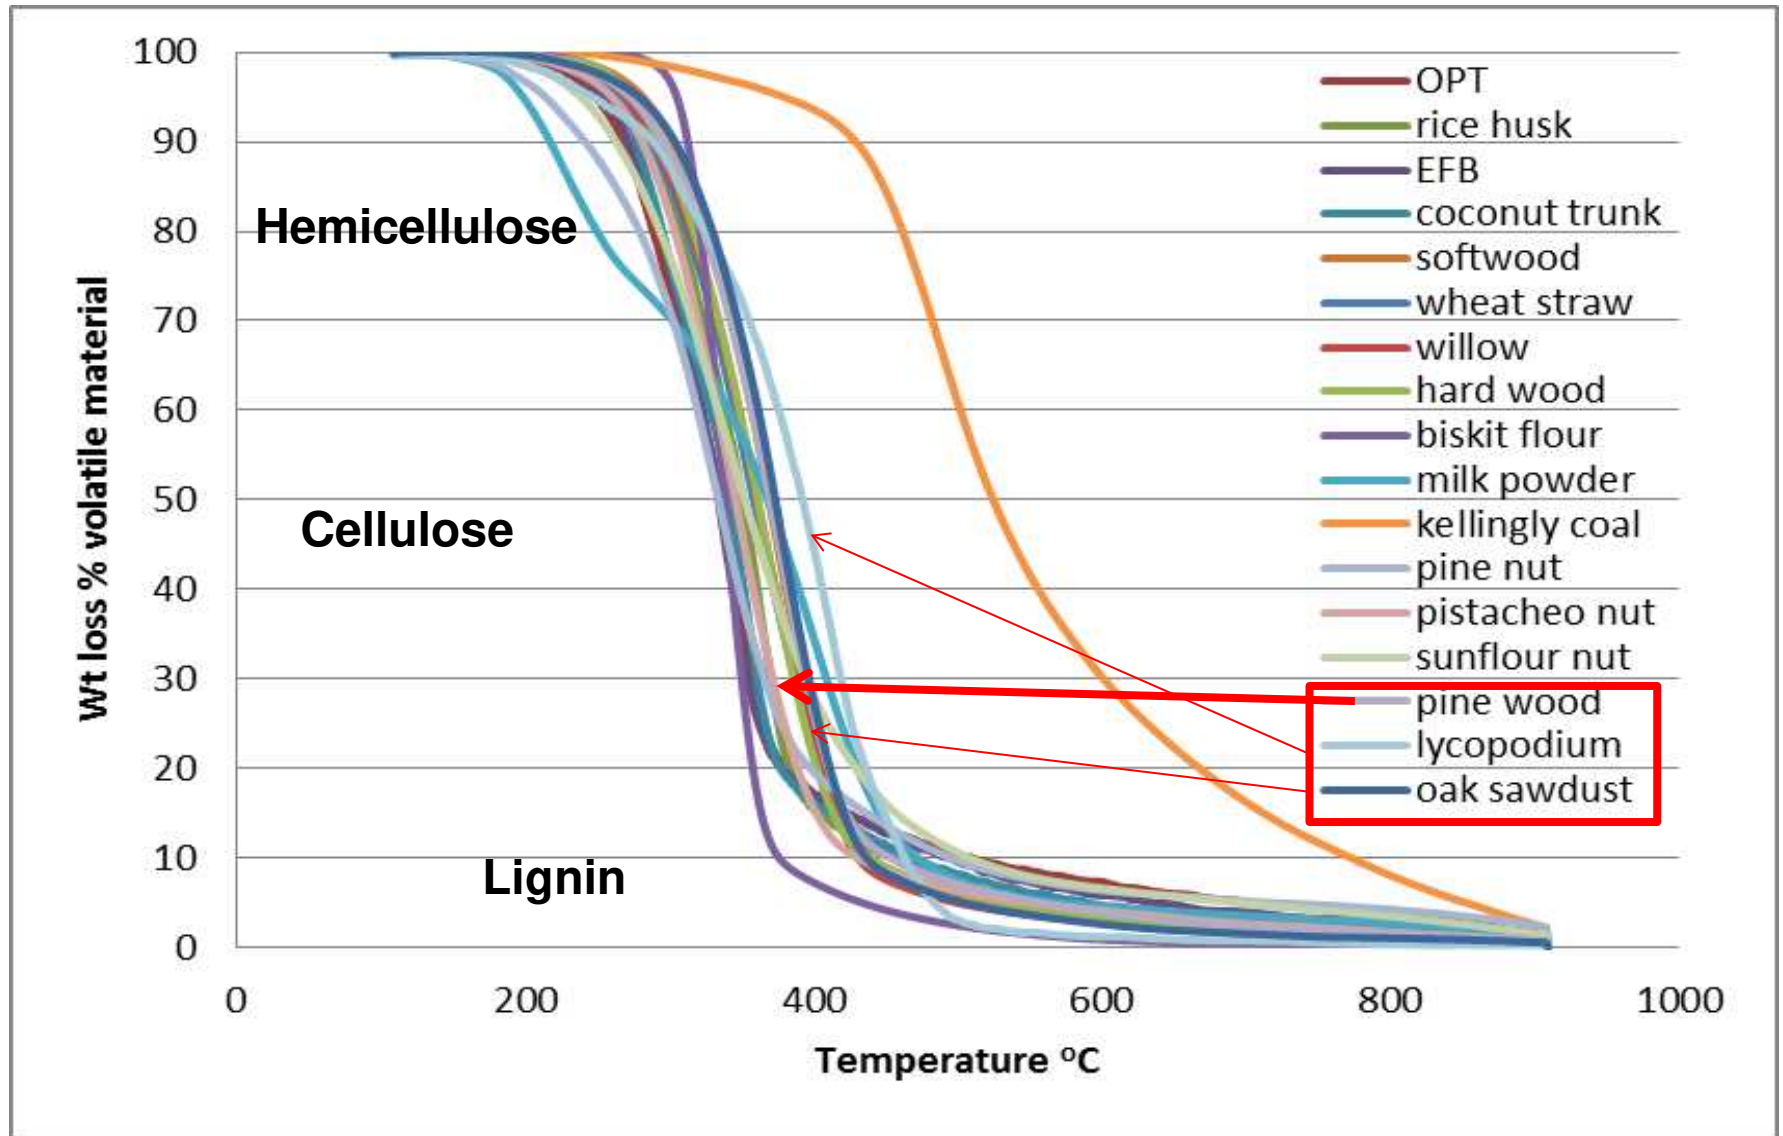

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 6

Biomass has lost 90% of its volatiles by 400°C compared with only 10% loss of volatiles for coal. Combustion air in coal burners is preheated to around 300°C where there is typically 30% volatile of volatiles in biomass flames will make a large difference in the flame structure compared with coal flames. Early release of volatiles is also crucial in the explosion hazards and in the biomass reactivity.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 23

Initial equipment was for the A/B dust explosion classification apparatus with a perspex tube.

Visual determination of a flame is difficult and dependant on the observer's criteria, therefore the apparatus was modified to enable pressure rise and flame speed measurement (as in EU gas lean limit tests).

The combustion chamber is a 1.04L vertical polycarbonate cylinder (L=322mm, D=61mm 1.04L + 0.06L in cup) into which a 7 barg blast of air is introduced at the base from a 0.05L vol. This gives 1.5L of air in total at STP, which is used to convert the g of dust used into g/m³.

Ignition is achieved by an arc ignition source, which is continuous.

The top of the tube is covered with aluminium foil secured with a locking ring that closes the tube. This bursts at 0.45 barg

The modified tube has a pressure transducer and three thermocouples have been fitted at 50mm, 100mm and 150mm for flame speed measurements. High speed video is also used to record the flame.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 24

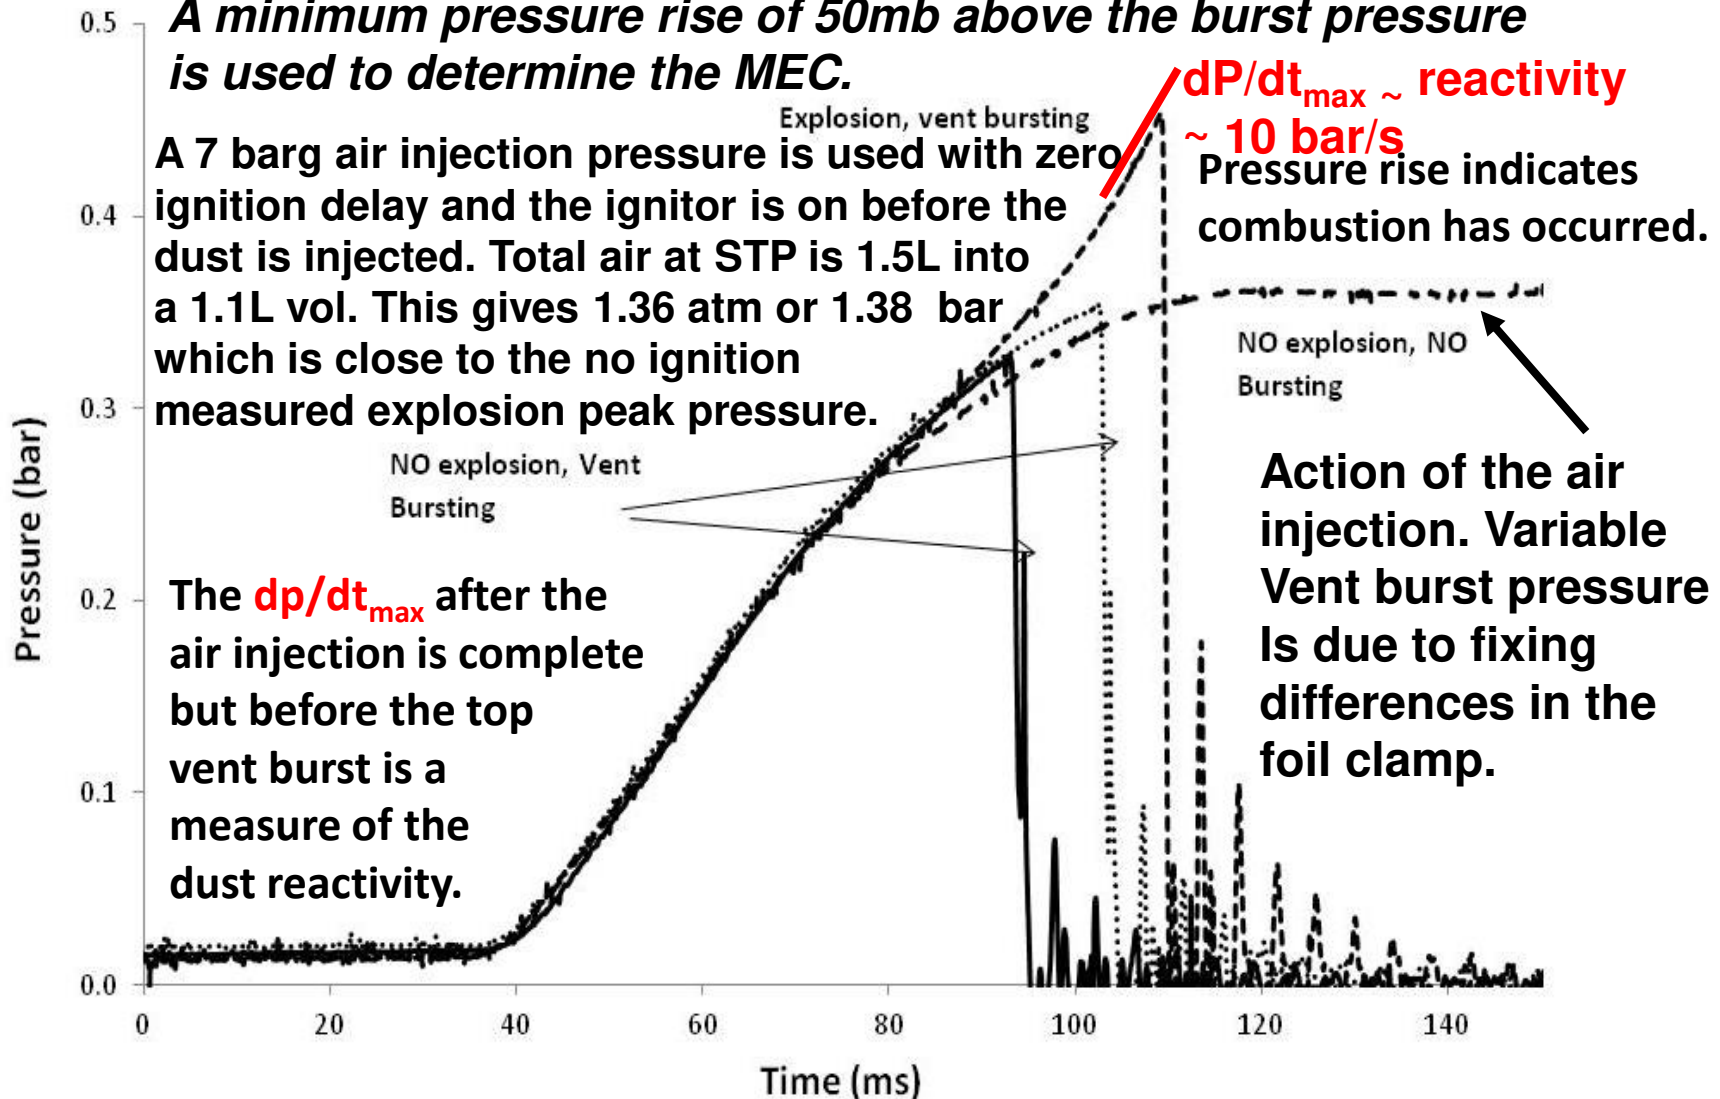

Huescar et al. IX ISHPMIE, Krakow, 2012

A minimum pressure rise of 50mb above the burst pressure is used to determine the MEC.

A 7 barg air injection pressure is used with zero ignition delay and the ignitor is on before the dust is injected. Total air at STP is 1.5L into a 1.1L vol. This gives 1.36 atm or 1.38 bar which is close to the no ignition measured explosion peak pressure.

The dp/dt_{max} after the air injection is complete but before the top vent burst is a measure of the dust reactivity.

**$dp/dt_{max} \sim$ reactivity
 $\sim 10 \text{ bar/s}$
Pressure rise indicates combustion has occurred.**

Oak sawdust

Sieved Size fraction	<63 μm	63 – 150 μm	150 – 300 μm	<500 μm
$D_{0.1}$	12.8 μm	62.7	181	62.8
$D_{0.32}$ Size with same surface area	23.9	82.2	303	109.3
< 100 μm	~85%	~30%	~ 5%	~ 15%
MEC Hartmann \emptyset	0.20	0.4	1.4	0.6

The oak dust MEC was very lean for the size sieved to <63 μm where the measured particle size was ~85% <100 μm . As the proportion of fines (<100 μm) decreased the MEC increased and was 1.4 for the most coarse dust.

This indicates that the flame propagated in the fine dust and the larger particles were heated by the post flame gases and then released volatiles that burnt. For coarse powders the MEC was for rich mixtures and this would gasify the post flame coarse particles.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

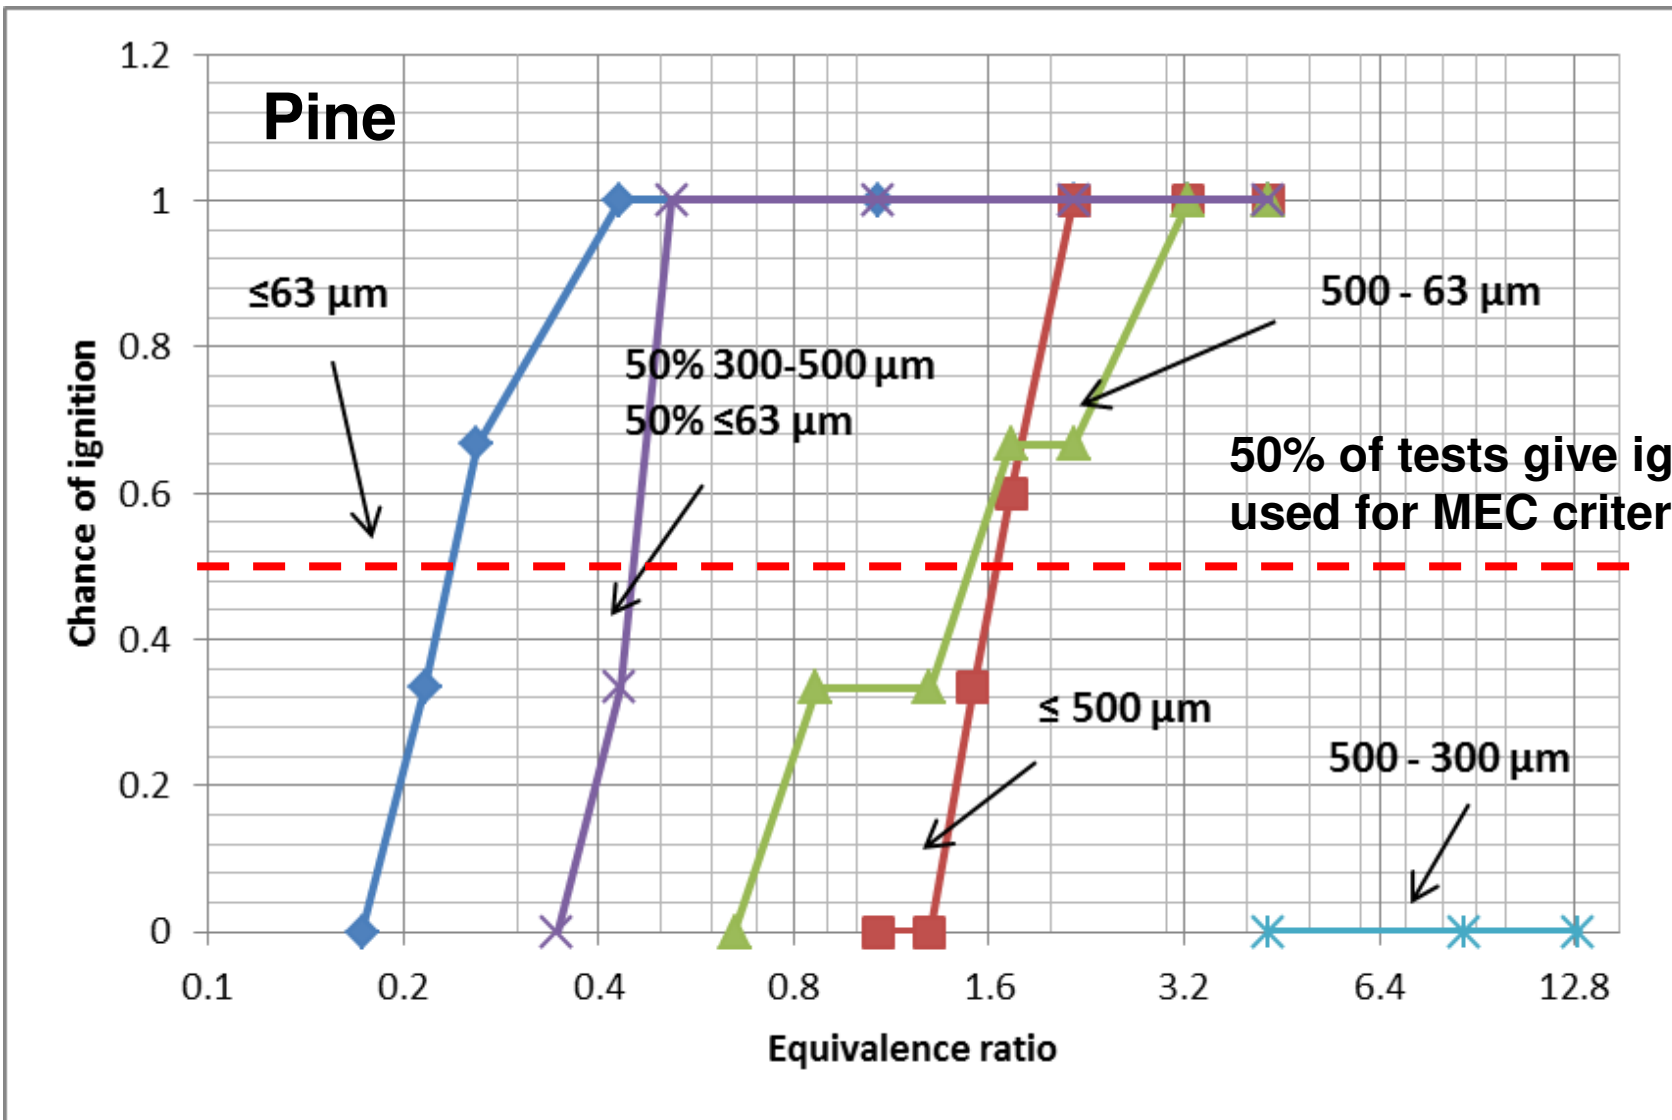

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 26

The differences in MEC between oak and pine dusts was due to differences in the actual particle size distribution for the same sieve size. It was not due to any chemical differences in the particles.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
 100mm School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 29

For rich mixtures the initial flame front before the Hartmann vessel vent burst is the only flame that propagates at the injected concentration.

Once this flame bursts the vent, the flame exits the top of the tube and then there is a second flame in the tube that is burning dust not burnt in the first flame due to the lack of air. This flame was faster than the first flame. This second flame is leaner than the first flame due to the air flow into the explosion tube after the vent bursts.

Air then continues to diffuse in and mix with the unburnt dust until there was a third flame and this has a lower flame speed due to leaner mixtures.

FLAME DEVELOPMENT IN PULVERISED BIOMASS FOR FINE PARTICLES.

Slatter, D.J.F., Saeed, M.A., Huéscar-Medina, C., Andrews, G.E., Phylaktou, H.N. and Gibbs, B.M.
School of Chemical and Process Engineering, University of Leeds, Leeds, LS2 9JT, UK. 31

Lycopodium powder, flame propagation ($\text{Ø}=1= 122.1\text{g/m}^3$) 0.05g,
 37.5g/m^3 , $\text{Ø}= 0.307$, mass mean particle size $32\ \mu\text{m}$.

Note that in the ISO $1\ \text{m}^3$ we have measured spherical turbulent flame speeds for the same lycopodium powder at $\text{Ø} = 0.31$ of 3 m/s.

Here the flame speed is 7 m/s.

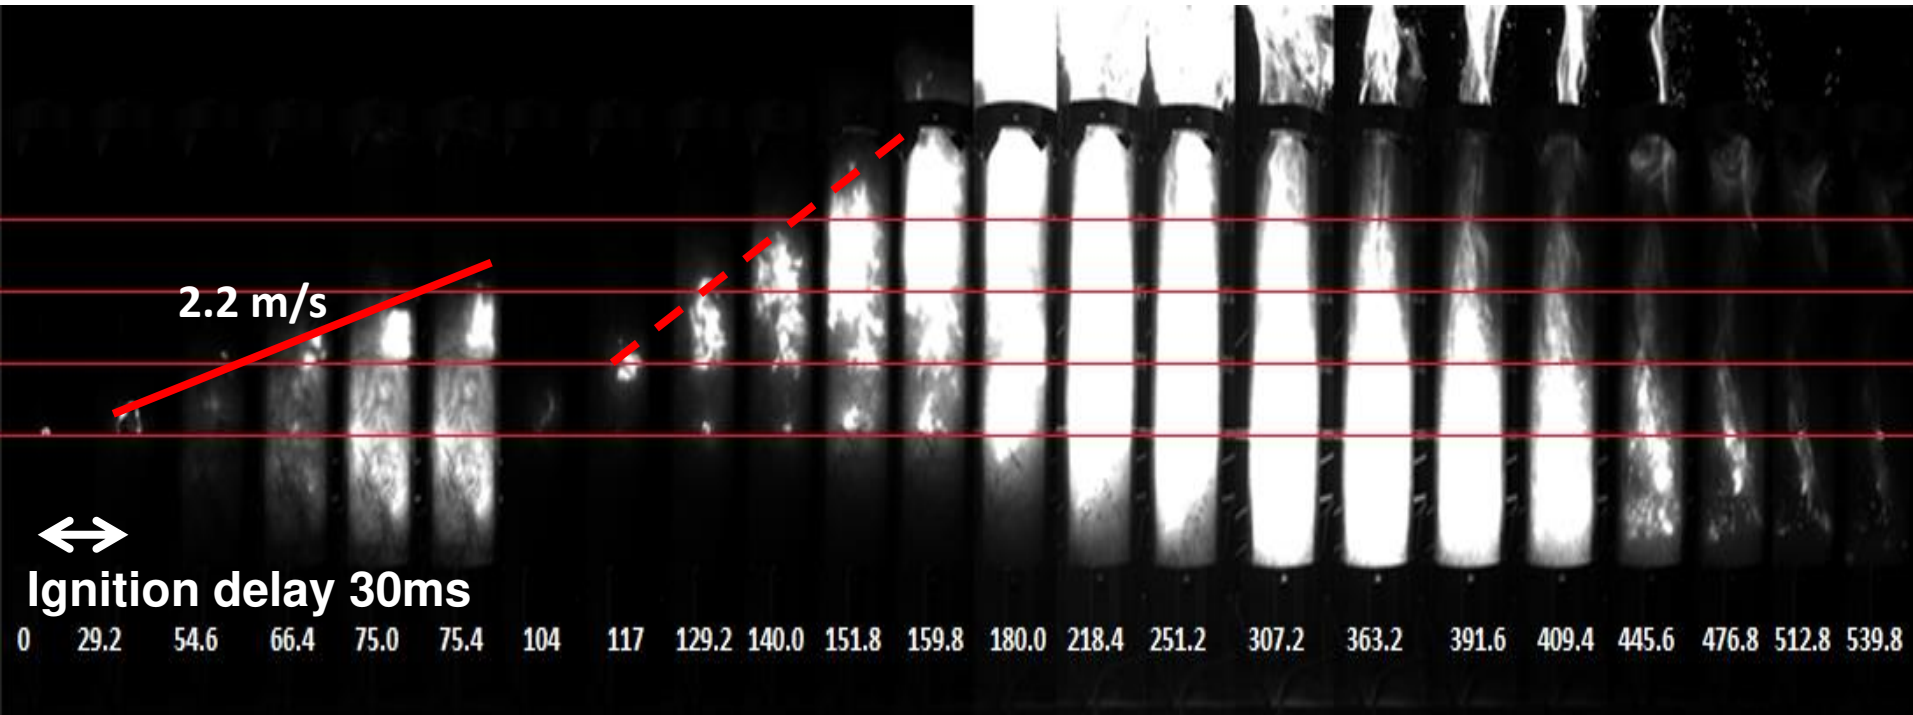

The higher value is due to the effect of the tube configuration with an L/D of 5.3, where it is known that the flame preferentially expands in the axial direction.

The time from the start of injection to the video observation of the start of flame propagation for oak sawdust. The size fractions were achieved by sieving. Fine particles have the lowest delay and the presence of fines with coarse particles reduces the overall ignition delay.

11th ECCRIA (European Conference on Coal Research and its Applications)
5th-7th September 2016, University of Sheffield, UK

For fine particles <63 μm sieve size the ignition delay was small.

A consequence of this is that there is little time for the injected dust and the air in the Hartmann tube to mix.

Also the turbulence decays with time from start of injection and hence fine particles will propagate at a higher turbulence level than for coarse particles.

The long ignition delay for coarse particles will lead to greater mixing time and hence the injected equivalence ratio could be close to the flame propagation equivalence ratio.

It was noted that all of the videos showed greater obscuration (caused by dust) ahead of the flame propagation.

Also observations of the dust dispersion using scattered light indicates that at the time of ignition the dust has not penetrated the full volume of the vessel and these videos indicate that the dust may have only penetrated 2/3 of the vessel length. This makes the mixture locally richer.

As this only occurs for fine particle size, due to the short ignition delay, it may be that the very lean MEC for fine particles is an experimental error and that for fine dusts an artificial ignition delay should be imposed. The authors have shown that 60 ms delay gives a richer MEC for fine mixtures.

Thus there are two opposing effects and the local equivalence ratio at the flame front need direct obscuration measurements to resolve these issues.

High speed video study of dust explosions in Hartmann equipment

Bagasse < 63 μm

(Even propagation of dust, efficient ignition)

Dust dispersion

Ignition

150 < Bagasse < 300 μm

(Uneven distribution with delayed ignition)

Ignition

Comparison between fine and coarse bagasse dust in the dust dispersion progress and ignition

Evidence is that the dust is not dispersed through the volume of air at the time of ignition – does this mean the measured MEC are too lean as there is stratified combustion so that the mixture that ignited is richer than the mean mixture?

But why would this only be a problem for HCO dusts?

Flame propagation mechanism for coarse dusts.

The MEC data indicates that the lean limit becomes richer for increase in particle size.

The explanation for this is that the flame front propagates in the fine particles, so that if the proportion of fine particles is low, as in dust with large mean particle size, then richer mixtures are required to give a flammable mixture in the fine fraction.

The explosion induced wind ahead of the flame cause the fine fraction and coarse fractions to separate and this leaves the coarse particles behind the fine particle flame front, where the dust is heated and gasified when the overall mixture is rich.

Experiments by the authors on the ISO 1 m³ dust explosion vessel also support this mechanism.

K_{st} vs. burnt equivalence ratio for different sized fractions steam exploded pine wood (BP)

The lean limit becomes richer as the particle size increases, as shown for work on the Hartmann equipment. The reason is that the mixtures have a wide range of sizes with around 10 – 20% fines (<100μm). **The flame propagates in the fine particles and the larger particles burn in the post fine flame hot gases. However, the fines are ~ 10 - 20% of the mass and so the overall mixture is rich for the fines to be flammable. This is the mechanism of combustion of coarse biomass.**

- 10. Flame propagation mechanism for coarse particles**
- 11. Conclusions**

Conclusions

- 1. Coarse particles of oak and pine will explode. The main reason is the presence of a wide size distribution with a significant fine fraction in all the coarse fractions.**
- 2. The reactivity of coarse particles is very low relative to fine particles. They act mainly as a heat sink that lowers the flame temperature, which lowers the reactivity.**
- 3. The mechanism of coarse particles propagating a flame is for the fine fraction to propagate the flame and for the coarse fraction to lag behind the flame front and be heated and gasified by the initial flame front.**
- 4. Flammability is then controlled by the fine fraction so that the overall mixture has to be very rich to generate sufficient fine fraction mass for the fine fraction to be flammable.**
- 5. Coarse fractions have an ignition delay which gives time for the dust and air to mix. Fine fractions ignite immediately and may propagate in a mixture that is locally rich and thus to have an artificially low MEC.**
