10 **Abstract**

11 An analysis is provided of the various models that have been proposed to account for the manner  
12 by which added NaCl or Na<sub>2</sub>SO<sub>4</sub> promotes the uptake of reactive on cellulosic fibres. Although  
13 conventionally, mathematical interpretations of isothermal equilibrium dye adsorption data are  
14 employed to describe the mechanism by which reactive dye adsorption occurs, such an approach  
15 does not satisfactorily explain why reactive dyes display inherently low uptake on cellulosic fibres in  
16 the absence of added inorganic electrolyte, nor does it explain why added inorganic electrolyte is so  
17 effective in promoting dye uptake.

18  
19 **Highlights**

- 20
- 21 • the role of inorganic electrolyte in reactive dye application is modelled
  - 22 • interstitial water is used to show that added electrolyte reduces dye solubility
  - 23 • added electrolyte promotes dye aggregation

## 26 1 Introduction

27 This paper concerns the role of some of the auxiliaries that are used in the application of dyes to  
28 textile fibres from aqueous dyebaths using immersion processes. Although various types of auxiliary  
29 are available that offer different kinds of assistance to immersion dyeing processes, the manner by  
30 which many auxiliaries function is unclear (1). In view of the enduring popularity of cotton and other  
31 cellulosic fibres a critical analysis was undertaken (2) of published work relating to the role of the  
32 most important auxiliary utilised in the exhaust dyeing of cellulosic fibres with direct dyes, namely  
33 inorganic electrolyte (either NaCl or Na<sub>2</sub>SO<sub>4</sub>). This resulted in a theoretical model being devised to  
34 explain the role of added NaCl or Na<sub>2</sub>SO<sub>4</sub> in the application of direct dyes (3). According to this  
35 model, which invoked the concept of interstitial water, the addition of inorganic electrolyte to the  
36 dyebath promotes dye aggregation which reduces the solubility of the dye in the dyebath, so that  
37 the inherent preference of the highly soluble dye to favour the aqueous phase shifts towards the  
38 fibre phase and, therefore, dye uptake is promoted; two equations were derived to interpret this  
39 theoretical model of direct dye adsorption (3). Subsequently, it was shown that the same theoretical  
40 model could also be used to explain the promotional effect which reducing the liquor ratio used for  
41 dyeing has on the uptake of direct dyes on cellulosic fibres (4). The two theoretical models were  
42 utilised to interpret the results obtained when three commercial grade direct dyes were applied to  
43 cotton using different liquor ratios in both the absence and presence of added NaCl (5). This latter  
44 study (5) demonstrated that because reducing the liquor ratio used for dyeing and adding inorganic  
45 electrolyte to a direct dye dyebath achieve the same outcome, namely promotion of direct dye  
46 uptake, it is possible to dye cotton to realistic depths of shade using direct dyes in the absence of  
47 added inorganic electrolyte through the use of very low liquor ratios.

48

49 The objectives of the work described in this part of the paper were to clarify the manner by which  
50 added inorganic electrolyte influences reactive dye uptake on cellulosic substrates.

51

## 52 2 reactive dyes for cellulosic fibres

53 By way of introduction, reactive dyes are one of five classes of dye (direct dyes, sulphur dyes, vat  
54 dyes, azoic colorants and reactive dyes) that can be applied to cotton and other cellulosic fibres  
55 using immersion dyeing processes. Different conditions (pH, temperature, etc.) are employed to  
56 apply the five types of colorant to cellulosic fibres and the characteristic attributes of the resulting  
57 dyeings (eg fastness, brightness, etc.) vary for the five classes of dye. However, for each of the five  
58 types of dye, inorganic electrolyte, in the guise of either NaCl or Na<sub>2</sub>SO<sub>4</sub>, must be added to the  
59 aqueous dyebath in order to achieve satisfactory levels of dye uptake; in the case of reactive dyes,  
60 the added electrolyte also promotes the extent of dye-fibre fixation (ie covalent fixation of the dye to  
61 the substrate).

62

63 The use of reactive dyes for cellulosic fibres has enjoyed virtually continuous growth since their  
64 commercial introduction ~60 years ago, which stemmed from the ground-breaking research of  
65 Stephen and Rattee (6-8). Consequently, global consumption of the other four dye classes has  
66 declined and reactive dyes nowadays account for ~ 55-60% of global dye consumption for cellulosic  
67 fibres (2).

68

69 The development of reactive dyes, as well as their chemistry and application to cellulosic fibres,  
70 have received considerable attention [see for example (6-25)]. In essence, the vast majority of  
71 reactive dyes are non-metallised azo structures, although metallised azo dyes as well several non-  
72 azo dye classes are represented, as exemplified by C.I. Reactive Red 198, C.I. Reactive Red 120  
73 and C.I. Reactive Blue 2.

97 In essence, reactive dyes comprise a chromogen (eg azo, AQ, etc.) that contains one or more  
98 substituted aromatic rings which carry sulfonate/sulfonic acid groups, to which is attached a reactive  
99 system that contains one or more electrophilic groups that enable the dyes to form a covalent bond  
100 with nucleophilic hydroxyl groups in the cellulosic substrate. A wide range of different types of  
101 reactive dye are commercially available for cotton and other cellulosic fibres, including  
102 monofunctional types that contain either a single reactive group or two, equivalent reactive groups,  
103 bifunctional dyes that contain two reactive systems per dye molecule and include both  
104 homobifunctional types which carry identical reactive systems and heterobifunctional reactive dyes  
105 that comprise different types of reactive system, as well as (commercially-rare) polyfunctional  
106 reactive dyes. Owing to differences in the dyeing behaviour of different types of reactive dye on

107 cellulosic substrates, dye makers commonly specify optimal application conditions (temperature,  
108 electrolyte concentration, pH, etc.) for their particular range(s) of reactive dyes.

109

110 From a structural perspective, reactive dyes are essentially long, planar, anionic molecules  
111 solubilised by one or more ionised sulfonate groups. As such, reactive dyes bear a close structural  
112 resemblance to direct dyes and, therefore, it is not surprising that in the absence of dye-fibre  
113 reaction (ie prior to the dye forming a covalent reaction with the cellulosic fibre), the adsorption of  
114 reactive dyes on cellulosic fibres is assumed to occur in a manner analogous to that of direct dyes  
115 (25). The mechanism by which added inorganic electrolyte promotes reactive dye uptake prior to  
116 dye-fibre fixation is also assumed to be analogous to that described for direct dye uptake (25).

117

#### 118 *2.1 dye-fibre reaction*

119 The dyes are applied under aqueous alkaline (eg NaOH, Na<sub>2</sub>CO<sub>3</sub>) conditions so as to deprotonate  
120 the cellulosic hydroxyl groups (Cell-OH) and generate the far more strongly nucleophilic, ionised  
121 hydroxyl groups (Cell-O<sup>-</sup>; aka *cellulosate anions*) within the substrate. The two most commercially  
122 exploited types of covalent reaction between reactive dyes and cellulosic substrates are nucleophilic  
123 addition to an alkene and aromatic nucleophilic substitution. Because, at the end of the immersion  
124 dyeing process, the chromogen is covalently bound to the fibre then dyeings on cotton and other  
125 cellulosic fibres obtained using reactive dyes characteristically display excellent fastness to wet  
126 treatments (eg washing, perspiration, etc.).

127

#### 128 *2.2 dye fixation*

129 From the viewpoint of dye-fibre systems in general, the term *fixation* can be defined as *the*  
130 *proportion of dye that was originally applied to a substrate which remains on the substrate after*  
131 *dyeing and associated processes, such as wash-off* (25). However, in the case of reactive dyes, the  
132 term *fixation* is generally acknowledged as referring explicitly to the proportion of (reactive) dye  
133 applied to a substrate (eg cotton) that is covalently bound to the substrate at the end of dyeing (25).

134 The related term *fixed dye* describes reactive dye that has become covalently attached (ie fixed) to  
135 the fibre during the course of dyeing.

136

### 137 2.3 dye hydrolysis

138 As mentioned, reactive dyes are applied to cellulosic fibres under aqueous, alkaline conditions, so  
139 as to optimise dye-fibre reaction via the generation of the strongly nucleophilic, ionised hydroxyl  
140 groups within the substrate. Unfortunately, these conditions result not only in dye fixation (ie  
141 covalent bond formation with the substrate) but also unwanted alkali-induced hydrolysis of the  
142 reactive dye. This confers inherently low levels of dye-fibre fixation efficiency upon all types of  
143 commercial reactive dyes. Indeed, as dye-fibre fixation and dye hydrolysis take place concurrently  
144 during all immersion reactive dyeing processes, the extent of dye fixation achieved using reactive  
145 dyes is characteristically quite a distance from 100%. For example, dye-fibre covalent bonding  
146 efficiencies of 57-76% and 50-68% for medium depth (3% omf) and full depth (6% omf) dyeing,  
147 respectively, were recorded for six types of reactive system (26). In the context of such alkali-  
148 induced dye hydrolysis, the term *unfixed dye* is the antonym of *fixed dye* and, unsurprisingly,  
149 describes reactive dye that is not covalently attached to the substrate during dyeing. However, in  
150 terms of reactive dyeing, there are two types of unfixed dye, namely hydrolysed dye that is no  
151 longer capable of covalently attaching to the fibre as well as reactive dye which for some reason or  
152 other was not covalently bound to the fibre during application, and which often is referred to as  
153 *unreacted dye*.

154

155 Alkali-induced dye hydrolysis has far-reaching economic and environmental consequences. Since  
156 dye hydrolysis always accompanies dye-fibre fixation then hydrolysed dye, as well as any unreacted  
157 dye, will be present in both the residual dyebath and in the final dyed material. The amount of such  
158 undesirable hydrolysed (ie non-reactive) dye and non-covalently bound reactive dye present in the  
159 dyeing at the end of dye application can be of the order of ~30-50% of the dye applied. The fixation  
160 efficiency of a given commercial range of reactive dyes is an important consideration from the  
161 viewpoint of the dyer, since high dye-fibre fixation is obviously preferable in terms of the economics

162 of exhaust dyeing. High fixation efficiency will also lead to lower amounts of residual, unfixed dye in  
163 dyehouse wastewater, which will serve to reduce environmental loads and lower wastewater  
164 treatment costs. Several methods can be used to determine the extent of dye fixation [eg (27-30)].

165

#### 166 *2.4 wash-off*

167 Owing to the intrinsic inefficiency of dye-fibre fixation imparted by dye hydrolysis, the immersion  
168 application of reactive dyes to cellulosic fibres comprises a two-stage process, namely, the *dyeing*  
169 *stage* in which the reactive dye is applied to the substrate under aqueous alkaline conditions to  
170 promote dye-fibre fixation, which is followed by the *wash-off stage* in which the ensuing dyed  
171 material is subjected to a rigorous, aqueous treatment to remove unfixed dye from the dyeing that  
172 arises primarily from the concurrent dye hydrolysis that takes place during dyeing. It is important  
173 that all un-reacted and non-reactive dye is removed from the dyed material to avoid the loss of  
174 vagrant dye molecules from the dyeing during subsequent wet treatments, such as domestic  
175 laundering, which otherwise, will result in the ensuing dyeings displaying low fastness to wet  
176 treatments.

177

#### 178 *2.5 wastewater*

179 In the dyeing of cellulosic fibres using reactive dyes, the wash-off stage is as vitally important as the  
180 dyeing stage in terms of the quality of the dyeing achieved (hue, levelness, fastness, etc.). Wash-off  
181 also contributes significantly to the overall effluent load generated during dyeing because of the  
182 presence of residual unfixed dye in the wastewater, the high level of residual electrolyte that is  
183 present in the dyed fibre at the end of the dyeing stage and also because of proprietary wash-off  
184 agents that are used in the wash-off process to expedite unfixed dye removal. Thus, both the dyeing  
185 stage and the subsequent wash-off stage characteristically generate very large amounts of  
186 wastewater that contains residual hydrolysed dye, unreacted dye, as well as very high levels of  
187 inorganic electrolyte and other dyeing auxiliaries. As such, reactive dyeing wastewater typically  
188 presents considerable environmental and economic challenges, as it is remarkably resilient to

189 biodegradation. Whilst many effluent treatment strategies have been considered [eg (31-35)], the  
190 treatment of reactive dyeing wastewater is especially complex and routinely consumes large  
191 amounts of both energy and chemicals owing to the presence of high levels of NaCl or Na<sub>2</sub>SO<sub>4</sub> [eg  
192 (36-40)]. The pronounced salinity of reactive dye wastewater has prompted the adoption of  
193 treatments that remove electrolyte for reclamation/disposal and enable recycling of some process  
194 water [eg (41-46)].

195

### 196 **3 added electrolyte in the dyeing of cellulosic fibres with reactive dyes**

197 The use of added electrolyte to promote the uptake of reactive dyes onto cotton (and other cellulosic  
198 fibres) dates from the introduction of the first range of commercial reactive dyes (the dichlorotriazinyl  
199 *Procion M*; ICI) in 1956. Although numerous ranges of reactive dye for cellulosic fibres have been  
200 marketed by many dye makers, and a variety of different types of reactive system utilised, the  
201 immersion application of all commercial ranges of reactive dye to cellulosic fibres routinely entails  
202 the use of significant levels of added inorganic electrolyte in the form of sodium sulfate or sodium  
203 chloride.

204

205 Despite the quite remarkable levels of research interest that both the chemistry and application of  
206 this dye class have attracted over several decades, the primary focus of the very large body of  
207 patents and papers that relate to reactive dyes and their application, has been the development of  
208 reactive systems from the viewpoint of increasing dye-fibre fixation efficiency. Indeed, neutral  
209 observers could be forgiven for assuming that the very rationale for utilising astonishingly large  
210 amounts of added electrolyte in exhaust dyeing figured very little, if at all, in the dye maker's  
211 development aspirations for reactive dyes.

212

213 Whilst the amount of electrolyte that is used in the immersion application of reactive dyes to  
214 cellulosic fibres varies according to the type of dye and amount of dye applied, an estimation can be  
215 made of the amount of inorganic electrolyte that is likely to be consumed globally. The exhaust  
216 application of this dye type to cellulosic fibres is carried out typically in the presence of between 10-

217 30  $\text{gl}^{-1}$  NaCl, with upto 50  $\text{gl}^{-1}$  for lower substantivity dyes, upto 80  $\text{gl}^{-1}$  for low substantivity  
218 vinylsulfone dyes (47) and 100  $\text{gl}^{-1}$  of NaCl or  $\text{Na}_2\text{SO}_4$  in the case of dark shades (48). If it is  
219 assumed that an average liquor ratio of 1:8 is utilised in exhaust dyeing processes and that all of the  
220 ~50-55% of global cellulosic fibre production in 2015 was dyed using reactive dyes (2) employing an  
221 immersion process, then the dyeing of the  $\sim 15 \times 10^6$  T of cellulosic fibre that was produced using  
222 reactive dyes in the presence of 50  $\text{gl}^{-1}$  added NaCl or  $\text{Na}_2\text{SO}_4$  would have consumed  $6 \times 10^6$  T of  
223 added inorganic electrolyte. Despite the somewhat overly simplistic approach adopted in this  
224 estimate and its inherent imprecision, it nevertheless provides an indication of the sizeable amounts  
225 of added inorganic electrolyte that are likely to be consumed globally in the immersion dyeing of  
226 cellulosic fibres using reactive dyes. In this context, the level of electrolyte usage described above  
227 corresponds to the consumption of  $\sim 0.4$  T of NaCl or  $\text{Na}_2\text{SO}_4$  per tonne of cellulosic fibre dyed,  
228 which is roughly  $1/3^{\text{rd}}$  of the 1.2 T of electrolyte per tonne of dyed cotton reportedly consumed in  
229 industry (2). As mentioned, because all of the inorganic electrolyte that is used during dyeing with  
230 reactive dyes must be removed from the dyed material, so as to achieve desired fastness levels, the  
231 habitual use of such high levels of inorganic electrolyte poses severe wastewater treatment  
232 problems.

233

234 As recounted, despite the plethora of patents, research papers and reports that have been  
235 published on reactive dyes and their application to cellulosic fibres over the past six or so decades,  
236 very little of this voluminous output has focussed on the fundamental nature of the role of added  
237 inorganic electrolyte in the immersion application of reactive dyes to cotton and other cellulosic  
238 fibres. However, one aspect of this abundant research activity has resulted in the introduction of so-  
239 called 'low salt' reactive dyes for cellulosic fibres.

240

241 For example, the high substantivity, bis(aminofluorotriazine) *Cibacron LS* (Ciba-Geigy) range [eg  
242 (23, 49, 50)] [now the *Novacron LS* range of Huntsman], which was launched in the mid 1990's and  
243 require  $1/3$  of the electrolyte required by standard reactive dyes (51), were first introduced in areas  
244 with arid climatic conditions and negative water balance (52). A more contemporary example of a

245 'low salt' reactive dye range is the trifunctional *Avitera SE* (Huntsman) (53, 54) dyes which offer  
 246 electrolyte savings of 20%. The use of such types of reactive dye offers potential savings in terms of  
 247 not only the amount of electrolyte consumed in dyeing but also the direct cost of the added NaCl or  
 248 Na<sub>2</sub>SO<sub>4</sub>, as exemplified by the data shown in Table 1 (51).

249

250 Table 1 comparison of electrolyte usage for conventional reactive dye and *Novacron LS* dye; 10,000 kg  
 251 cotton; 1:15 liquor ratio (51)

|  | conventional | <i>Novacron LS</i> |
|--|--------------|--------------------|
| amount of liquor/ l                                      | 150,000      | 150,000            |
| amount of electrolyte/ gl <sup>-1</sup>                  | 80           | 20                 |
| total amount of electrolyte per day/ kg                  | 12,000       | 3,000              |
| total amount of electrolyte per year/ kg                 | 3,000,000    | 750,000            |
| NaCl cost/ US\$ (US\$ 0.1 kg)                            | 300,000      | 75,000             |
| Na <sub>2</sub> SO <sub>4</sub> cost/ US\$ (US\$ 0.2 kg) | 600,000      | 150,000            |

252

253

254 Despite such developments in dye chemistry that utilise increased dye-fibre reaction efficiency to  
 255 achieve what, in effect, are only moderate reductions in the amount of added electrolyte employed  
 256 in the immersion application of reactive dyes to cellulosic fibres, the vast majority of commercial  
 257 exhaust dyeing processes utilise 'conventional' reactive dyes that require the use of typically very  
 258 high amounts of inorganic electrolyte. As Table 1 shows, such widespread usage of conventional  
 259 reactive dyes in the immersion dyeing of cotton and other cellulosic fibres represents a major direct  
 260 cost, insofar as each of the 1.2 T of added NaCl or Na<sub>2</sub>SO<sub>4</sub> that is consumed per T of cotton dyed,  
 261 costs either US\$ 12 or US\$ 24, depending on whether NaCl or Na<sub>2</sub>SO<sub>4</sub>, respectively, is used in  
 262 dyeing, amounting to an annual electrolyte cost of US\$ 300,000 or US\$ 600,000. If such chemical  
 263 costs were applied to the estimated 6 x 10<sup>6</sup> T of added inorganic electrolyte that may have been  
 264 consumed in reactive dyeing in 2015, it is obvious that very large amounts of money (ie US\$

265 72,000,000 to US\$ 144,000,000) would have been expended on buying electrolyte. To this already  
266 high level of direct electrolyte expense must be added the substantial energy, water and chemical  
267 costs that must be incurred in treating the significant amounts of reactive dyeing wastewater that is  
268 contaminated by high levels of NaCl or Na<sub>2</sub>SO<sub>4</sub>.

269

270 The replacement of inorganic electrolyte with alternative compounds that promote reactive dye  
271 uptake has been investigated, as exemplified by the use of cationic surfactants, various chlorides  
272 and carboxylic acid salts (55), betaine (56), sodium edate (57, 58), trisodium citrate (59) and  
273 trisodium nitrilo triacetate (60); however, such an approach has not as yet enjoyed widespread  
274 commercial application.

275

276 In relatively recent times, the possibility of enhancing the uptake of reactive dyes on cotton (and  
277 other cellulosic fibres) by treating the substrate prior to dyeing with a quaternary amine  
278 (*cationisation*) or with aliphatic amino groups (*amination*) has received research attention [see (25)  
279 for a summary of such approaches]. In essence, the introduction of *N*-containing species via pre-  
280 treatment of the cellulosic substrate increases the basicity of the cellulosic material which enhances  
281 the substantivity of the treated substrate towards the anionic reactive dye; as such, immersion  
282 dyeing should therefore be achievable using reduced levels of added electrolyte. However, despite  
283 the often marked enhancement in dye substantivity that such pretreatments can impart, the  
284 approach does not enjoy broad commercial success, as treatments can, for example, promote ring  
285 dyeing and, also, dyeings can display alteration of hue, as well as reduced fastness to light and  
286 rubbing.

287

#### 288 **4 why is inorganic electrolyte used in the dyeing of cellulosic fibres with direct dyes?**

289 In essence, adding either NaCl or Na<sub>2</sub>SO<sub>4</sub> to a reactive dye dyebath increases the inherent low  
290 substantivity displayed by the dyes towards cellulosic fibres and, as a result, dye uptake is  
291 promoted. Both the characteristically low levels of dye-fibre substantivity displayed by reactive dyes  
292 in the absence of added electrolyte and the remarkable effectiveness of added inorganic electrolyte

293 in promoting dye uptake, can be attributed to the combined effects of their long, linear structure and  
 294 the presence of one (or most usually) more sulfonate groups which impart both anionicity and water  
 295 solubility. In the latter context, reactive dyes display characteristically high levels of water solubility,  
 296 as exemplified by values of 70-100  $\text{gl}^{-1}$  @ 20°C (61), 60-120  $\text{gl}^{-1}$  at 25°C (62), 70  $\text{gl}^{-1}$  @ 20°C (63)  
 297 and 50-100  $\text{gl}^{-1}$  @ 50°C (64) having been recorded for various types of commercial grade reactive  
 298 dye. Although such high aqueous solubility contributes to the renowned simplicity of the immersion  
 299 reactive dyeing process, it also means that the liquor ratio used for dyeing, which determines the  
 300 amount of water available in the dyebath, not only has a pronounced effect on both the rate and  
 301 extent of reactive dye uptake, but also influences the effectiveness with which added electrolyte  
 302 promotes dye uptake.

303

304 This is reflected in commercial immersion dyeing processes that are used to apply reactive dyes to  
 305 cellulosic fibres. The dyer manipulates the level of substantivity displayed by the dye towards the  
 306 substrate so as to ensure that uniform dyeings of the desired depth of shade are obtained within a  
 307 given dyeing time. To achieve this, a particular amount of added inorganic electrolyte is used in  
 308 combination with a particular liquor ratio (and at a given dyeing temperature). In this way, the  
 309 relative contributions that the added electrolyte and liquor ratio make to the overall level of dye-fibre  
 310 substantivity are regulated. Thus, a change in the liquor ratio selected for dyeing demands a  
 311 corresponding change in the amount of added electrolyte employed (and visa versa), so that a  
 312 particular degree of dye-fibre substantivity is achieved that is consistent with securing uniform  
 313 dyeings of the desired colour strength, within the required time frame.

314

315 Table 2 amounts of added electrolyte and alkali required for immersion dyeing using *Novacron FN* dyes (65)

316

| liquor ratio | electrolyte & alkali   | dye/% omf |     |    |    |    |    |    |
|--------------|------------------------|-----------|-----|----|----|----|----|----|
|              |                        | < 0.5     | 0.5 | 1  | 2  | 3  | 4  | ≥5 |
| < 1:6        | NaCl/ $\text{gl}^{-1}$ | 20        | 30  | 40 | 50 | 60 | 70 | 80 |

|       |   |     |      |      |      |     |     |     |
|-------|---|-----|------|------|------|-----|-----|-----|
|       | NaHCO <sub>3</sub> / gl <sup>-1</sup>       | 14  | 16   | 18   | 20   | 20  | 20  | 20  |
| < 1:8 | NaCl/ gl <sup>-1</sup>                      | 20  | 30   | 40   | 50   | 60  | 70  | 80  |
|       | NaHCO <sub>3</sub> / gl <sup>-1</sup>       | 10  | 12   | 14   | 16   | 18  | 20  | 20  |
| > 1:8 | NaCl/ gl <sup>-1</sup>                      | 30  | 40   | 50   | 60   | 80  | 90  | 100 |
|       | NaHCO <sub>3</sub> / gl <sup>-1</sup>       | 8   | 10   | 12   | 14   | 16  | 18  | 18  |
| < 1:6 | NaCl/ gl <sup>-1</sup>                      | 20  | 30   | 40   | 50   | 60  | 70  | 80  |
|       | NaHCO <sub>3</sub> / gl <sup>-1</sup>       | 10  | 10   | 5    | 50   | 5   | 5   | 5   |

|       | NaHCO <sub>3</sub> / gl <sup>-1</sup>       | 8   | 5    | 5    | 5    | 5   | 5   | 5   |
|       | NaOH 36°Bé/ cm <sup>3</sup> l <sup>-1</sup> | -   | 0.5  | 1    | 1.25 | 1.5 | 2   | 2.5 |

317

318 Dye manufacturers therefore commonly recommend the amount of inorganic electrolyte to be used  
 319 in dyeing as a function of the particular ratio selected for dyeing, as illustrated in the data shown in  
 320 Table 2 (65).

321

322 Hence, the two seemingly disparate variables of a reactive dye dyebath, namely the presence of  
 323 added electrolyte and the volume of the dyebath (ie liquor ratio used for dyeing), influence dye-fibre  
 324 substantivity and, thus, dye uptake. It therefore seems reasonable to suggest that the most likely  
 325 physical attribute of reactive dyes that might be affected by both added inorganic electrolyte and  
 326 liquor ratio is aqueous solubility.

327

328 Whilst the effect of liquor ratio on dye uptake in immersion dyeing processes in general has  
 329 received much attention and the role of liquor ratio in reactive dyeing has been widely studied, our  
 330 understanding of the manner by which liquor ratio influences dye uptake remains unclear (3). More  
 331 significantly (3), the combined effects of liquor ratio and added inorganic electrolyte on the uptake of

332 dye anions (eg reactive dyes, direct dyes, etc.) on cellulosic fibres has not been addressed. In the  
333 latter context, as mentioned, it has been shown in the case of the dyeing of cotton using commercial  
334 direct dyes, that the addition of inorganic electrolyte (3) and reduction of liquor ratio (4) impart the  
335 same promotional effect on dye uptake, as the two, apparently incongruent actions of adding  
336 electrolyte to the dyebath and reducing the liquor ratio used in dyeing, have the same result, namely  
337 that of encouraging dye aggregation in the dyebath, which reduces the solubility of the direct dye in  
338 the dyebath, which, in turn, increases the concentration gradient in the dyebath, resulting in  
339 increased dye uptake.

340

341 In view of these findings (3, 4) and the previously discussed assumption that prior to the reactive  
342 dye forming a covalent reaction with the cellulosic fibre, the adsorption of reactive dyes on cellulosic  
343 fibres is assumed to occur in a manner analogous to that of direct dyes, it seems reasonable to  
344 propose that in order to understand the manner by which added inorganic electrolyte promotes the  
345 uptake of reactive dyes on cellulosic fibres, the mechanism by which liquor ratio influences dye  
346 uptake must also be clarified.

347

#### 348 **5 current mechanistic views of the role of added electrolyte in the dyeing of cellulosic fibres** 349 **using reactive dyes**

350 Despite the widespread use of added electrolyte in the dyeing of cellulosic fibres, not only in the  
351 case of reactive dyes but also other types of both anionic dye (direct dyes) and dye precursors  
352 (azoic coupling components, leuco vat anions and sulphur anions), coupled with the fact that the  
353 mechanism by which added electrolyte promotes both the rate and extent of uptake of anionic dyes  
354 on cellulosic fibres has received considerable attention over many years, the precise nature of the  
355 promotional effect imparted by added inorganic electrolyte on reactive dye uptake has not been  
356 elucidated (2).

357

358 It may appear initially surprising, given the current dominance of reactive dyes in cellulosic fibre  
359 dyeing and the remarkable level of commercial development which this type of dye has enjoyed,

360 that very little research interest has attended the mechanism by which added electrolyte promotes  
361 dye uptake. This situation becomes perhaps more understandable when it is recalled that our  
362 knowledge of the mechanism by which added inorganic electrolyte promotes reactive dyeing is  
363 based on the findings of studies that were carried out into the mechanism by which added NaCl or  
364 Na<sub>2</sub>SO<sub>4</sub> promotes direct dye uptake on cellulosic fibres. Indeed, as mentioned, from the perspective  
365 of the thermodynamic treatment of the equilibrium adsorption of reactive dyes on cellulosic fibres, it  
366 is assumed that in the absence of dye-fibre reaction (ie prior to dye-fibre fixation), reactive dye  
367 adsorption occurs in a manner analogous to that of direct dyes (25). Unfortunately, contemporary  
368 views of the thermodynamics and kinetics of direct dyeing are founded mostly on detailed, elegant  
369 studies undertaken in the 1930's and 1940's (decades prior to the introduction of reactive dyes), that  
370 employed relatively few purified direct dyes (which nowadays enjoy limited current commercial  
371 usage) as well as very high liquor ratios. Furthermore, the precise nature of the mechanism by  
372 which direct dyes are adsorbed onto cellulosic fibres has not been satisfactorily resolved. Indeed,  
373 the observed inconsistencies between theoretically derived equations that attempt to describe  
374 experimentally derived observations can be attributed to the inherently complicated nature of direct  
375 dye-inorganic electrolyte interactions and a somewhat diffuse appreciation of the mechanism by  
376 which added inorganic electrolyte influences dye-fibre substantivity (2). It is therefore not surprising  
377 that our current understanding of the precise manner by which added electrolyte promotes reactive  
378 dye uptake on cellulosic fibres leave much to be desired.

379

380 In this context, several theories have been proposed to describe the promotional effect of added  
381 electrolyte on the uptake of direct dyes on cellulosic fibres, which, in turn, have been adopted by  
382 workers seeking to explain the role of added inorganic electrolyte in the immersion dyeing of  
383 cellulosic fibres with reactive dyes. Of these theories, the three that have gained most attention will  
384 be briefly discussed in the context of reactive dyes for cellulosic fibres.

385

### 386 5.1 electrical repulsion effects

387 Many researchers consider that the negative charge that is developed at the surface of cotton and  
388 other cellulosic fibres in water is lowered in the presence of inorganic electrolytes, which enables  
389 long-range repulsive forces operating between the negatively charged cellulosic substrate surface  
390 and the negatively charged dye anions in the dyebath to be reduced, thereby leading to enhanced  
391 dye uptake. For instance, Hildebrand (12), favoured the idea that reduced electrical repulsion  
392 expedites reactive dye uptake and also suggested that because polar media facilitates the formation  
393 of a transition state of the Meisenheimer complex type, added electrolyte may exert a positive effect  
394 on the rate of dye-fibre reaction. Lidyard *et al* observed that a reduction in electrolyte concentration  
395 led to greater repulsion between the anionic dye and the negatively charged cellulosic substrate,  
396 resulting in reduced substantivity (66). However, whilst the notion that added electrolyte promotes  
397 anionic dye uptake by lowering the electrical repulsion between the negatively charged cellulosic  
398 fibre and the dye anions, this particular explanation does not appear especially convincing in its own  
399 right, bearing in mind the poor relationship between the amount of electrolyte that is theoretically  
400 required to overcome the surface charge of cellulosic substrates and the amount of added NaCl or  
401 Na<sub>2</sub>SO<sub>4</sub> typically utilised in the exhaust dyeing of cellulosic fibres with anionic dyes (25). This is of  
402 especial significance with regards reactive dyes, for which upto 100 g l<sup>-1</sup> of added inorganic  
403 electrolyte can be employed in dyeing. For example, in a study of the effect of different electrolytes  
404 on the sorption of hydrolysed reactive dyes on cotton (67), it was concluded that whilst the observed  
405 increase in dye uptake that accompanied an increase in electrolyte concentration may be attributed  
406 to partial screening of the cellulosic fibre surface charge by the crowding of electrolyte cations at the  
407 cellulose-water interface, this theory did not explain the relative effectiveness of different electrolytes  
408 (eg NaCl, (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, LiCl) in modifying dye sorption at a given, equivalent, electrolyte  
409 concentration.

410

### 411 5.2 dye aggregation/reduced dye solubility

412 In the second part of this paper (2), which sought to establish the mechanism by which added  
413 electrolyte enhances the uptake of direct dyes on cotton, it was concluded that electrical repulsion

414 effects contribute little and that adding NaCl or Na<sub>2</sub>SO<sub>4</sub> to the dyebath encourages dye aggregation  
415 in the dyebath which reduces the aqueous solubility of the dye, so that the inherent predilection of  
416 the previously highly soluble dye to favour the aqueous phase shifts towards the fibre phase and the  
417 distribution of the dye between the dyebath and the fibre therefore favours the latter. Since it is  
418 assumed that the mechanism by which added electrolyte promotes reactive dye uptake prior to dye-  
419 fibre fixation is analogous to that described for direct dye uptake, then the effects of the added  
420 inorganic electrolyte on reactive dye uptake might also arise from the effects which increased dye  
421 aggregation and reduced solubility of the anionic reactive dyes in the dyebath have upon the  
422 distribution of the dye between the dyebath and the substrate.

423

424 In this context, the typically, long, planar structure of reactive dyes not only favours dye-fibre  
425 substantivity (47) but also explains the dye's remarkable proclivity to aggregate in aqueous solution  
426 via coplanar association, as is well-documented in the case of direct dyes [eg see (2, 25)]. As also  
427 observed for direct dyes (2), self-association of this kind is favoured by high dye concentrations and  
428 low temperatures, as well as the addition of inorganic electrolyte. By way of example, NaCl was  
429 found to increase the extent of aggregation of C.I. Reactive Blue 4 (68) and both C.I. Reactive Red  
430 180 and

431 C.I. Reactive Red 2 in aqueous solution (69). The aggregation tendency, in water, of  
432 triphenodioxazine dyes carrying vinylsulfone reactive centres was promoted by the addition of NaCl  
433 (70), whilst LiCl was found to be more effective than NaCl in terms of the dimerization of C.I.  
434 Reactive Blue 2 (71). Furthermore, the finding (62) that the adsorption capacity of several reactive  
435 dyes from aqueous solution onto activated carbon increased with increasing ionic strength was  
436 attributed to dye aggregation in solution, whilst the marked effect of NaCl upon the removal of C.I.  
437 Reactive Black 5 from solution using nanofiltration membrane was attributed to aggregation (72);  
438 similarly, the adsorptive capacity of C.I. Reactive Black 5 on various adsorbents were promoted by  
439 both NaCl and Na<sub>2</sub>PO<sub>4</sub> (73). Bredereck and Schumacher (74) observed that the aggregation, in  
440 solution, of twelve monoazo H-acid based reactive dyes containing both a monochlorotriazine and a  
441 vinylsulphone reactive system, was enhanced by the addition of electrolyte (Na<sub>2</sub>SO<sub>4</sub>) and also by

442 increasing dye concentration, the latter finding being also reported in the case of other reactive dyes  
443 (70), such as C.I. Reactive Blue 4 (68). Other types of electrolyte have been shown to promote  
444 reactive dye aggregation in solution, including  $\text{MgCl}_2$  and  $\text{MnCl}_2$  (75) whilst various electrolytes were  
445 found to promote the uptake of the hydrolysed form of four different reactive dyes on cotton (76).

446

447 As discussed in the case of direct dyes (2), the remarkable ability of both  $\text{NaCl}$  and  $\text{Na}_2\text{SO}_4$  to  
448 encourage reactive dye self-association in solution can be attributed to the added inorganic  
449 electrolyte counterions (ie  $\text{Na}^+$ ) screening the anionic charge derived from  $-\text{SO}_3^-$  groups on the dye  
450 anions, which reduces electrostatic repulsion between neighbouring charged dye anions and,  
451 thereby, promotes hydrophobic interaction between planar aromatic rings in adjacent reactive dye  
452 molecules. As  $\pi$ - $\pi$  interactions between aromatic regions in the dye molecules will be expedited by  
453 the screening of the anionic charge on the dye anions by the electrolyte counterions. dye-dye  
454 interactions that favour dye self-association. Such hydrophobic interaction, of which dye aggregation  
455 is a corollary, will be driven by the need for the surrounding water molecules to minimise their  
456 interaction with the reactive dye solutes and so diminish the extent to which water structure is  
457 disrupted by the dye molecules.

458

459 As ionisation of the reactive dye molecules will be suppressed as a consequence of both the strong  
460  $\pi$ - $\pi$  interactions operating between aromatic regions in neighbouring dye molecules and the  
461 screening of the  $-\text{SO}_3^-$  groups by the  $\text{Na}^+$  counterions, the dye molecules that are present within the  
462 dye aggregates (ie dye dimers, trimers,  $n$ -mers, etc.) will likely possess lower aqueous solubility  
463 than their monomolecularly dissolved reactive dye counterparts in the aqueous dyebath. Also,  
464 because hydrophobic interaction will result in less water being available to the dye aggregates in the  
465 dyebath, the aggregates will tend to coalesce and form particles (ie clusters of dye aggregates) that  
466 will constitute a dye dispersion within the aqueous dyebath. As a consequence of electrolyte-  
467 induced dye self-association, the concentration of reactive dye in solution in the dyebath will  
468 therefore be reduced, from which it follows that the addition of  $\text{NaCl}$  or  $\text{Na}_2\text{SO}_4$  to a reactive dye in  
469 solution will reduce the solubility of the dye, as indeed has been observed. For example, the

470 solubility of C.I. Reactive Black 8 and C.I. Reactive Blue 49 decreased as a function of KCl  
471 concentration (77) and the aqueous solubility of *Novacron FN* (Huntsman) reactive dyes is reported  
472 to be lowered from 100  $\text{g l}^{-1}$  in water at both 30°C and 60°C to 30  $\text{g l}^{-1}$  at 60°C in 60  $\text{g l}^{-1}$  aqueous  
473 electrolyte solution (65).

474

475 Thus, as proposed in the case of direct dyes (2), applying reactive dyes to cotton and other  
476 cellulosic fibres in the presence of added NaCl or  $\text{Na}_2\text{SO}_4$  can be considered as a process of  
477 controlled dye precipitation onto the substrate, in that the amount of added inorganic electrolyte  
478 used is such as to induce the formation of a dispersion of dye particles in the aqueous dyebath  
479 whilst avoiding flocculation of the dye.

480

481 However, as discussed below, despite the fact that electrolyte-induced reactive dye self-association  
482 may offer a realistic explanation as to the manner by which added inorganic electrolyte promotes  
483 reactive dye adsorption, the physical process of dye aggregation in solution and, more importantly,  
484 its encouragement by added inorganic electrolyte, cannot be accounted for satisfactorily using the  
485 physico-chemical models that have been proposed to describe reactive dye adsorption on cellulosic  
486 fibres.

487

### 488 *5.3 thermodynamics of dyeing*

489 For general accounts the reader is directed to (7, 15, 18, 22, 25, 78-80) and the references therein.

490

491 As the adsorption of reactive dyes onto cellulosic fibres prior to dye-fibre reaction is assumed to  
492 parallel that of direct dyes, the mechanism by which the dyes are adsorbed is also presumed to  
493 resemble that of direct dyes (2), being interpreted from equilibrium adsorption data using either  
494 Freundlich or Langmuir equations that assume a Donnan distribution of ions and invoke usage of  
495 the concept of fibre internal volume,  $V$  (25). However, as previously discussed in the case of direct  
496 dye adsorption (2), Freundlich-type and Langmuir-type interpretations of experimentally obtained  
497 equilibrium dye adsorption data differ fundamentally not only from the viewpoint of the nature of the

498 interactions that can occur between the adsorbing dye molecules and the substrate but also,  
499 importantly, in terms of the possible contribution that dye aggregation makes towards dye-fibre  
500 interaction and, therefore, the role of added inorganic electrolyte in dye adsorption. The generally  
501 poor correlation obtained between such theoretical interpretations of experimentally observed  
502 equilibrium dye adsorption data reflect the highly complex nature of dye-electrolyte-fibre interactions  
503 and a less than complete understanding of these fundamentally important aspects of dye  
504 adsorption. Furthermore, currently accepted physico-chemical models of reactive dye adsorption  
505 are unable to account for either the low uptake observed when the dyes are applied in the absence  
506 of added inorganic electrolyte or the marked promotional effect of added NaCl or Na<sub>2</sub>SO<sub>4</sub> on dye  
507 uptake; in part, such a situation can be attributed to a somewhat unclear understanding of the role  
508 of added electrolyte in dyeing.

509

510 In the latter context, as previously recounted (2), owing to the complicating effect of added NaCl or  
511 Na<sub>2</sub>SO<sub>4</sub> on dye adsorption, several thermodynamic models of direct dye adsorption on cellulosic  
512 fibres and, therefore, by extrapolation, that of reactive dyes, have been developed of which the  
513 *diffuse adsorption* model (81) is most widely accepted (25).

514

$$515 \quad K = \frac{[D]_f}{[D]_s} \quad 1$$

516

517 In essence (25, 80), such models seek to describe the partition of the dye between the fibre phase  
518 and the solution phase (ie dyebath) achieved under equilibrium conditions in terms of the  
519 thermodynamic standard affinity of the dye,  $-\Delta\mu^\theta$ , employing mathematical interpretations of Eq 1,  
520 where  $[D]_f$  is the amount of dye present in the fibre phase (ie the substrate) relative to the amount of  
521 fibre and  $[D]_s$  is the amount of dye in solution (ie the dyebath) relative to the amount of solution and  
522  $K$  is the equilibrium partition coefficient which describes the distribution of the dye between the  
523 dyebath,  $s$  and fibre,  $f$ , phases; the higher the value of  $K$  then the greater is the partition of the dye  
524 in favour of the fibre phase (ie  $[D]_f > [D]_s$ ) and the greater is the extent of dye uptake onto the

525 substrate. The second part of the paper (2) considers the consequences of using the same or  
526 different units for measuring values of  $[D]_f$  and  $[D]_s$ .

527

528 Whilst such mathematical treatments seek to account for the effects of temperature and inorganic  
529 electrolyte on dye equilibrium, the latter aspect of both direct dye and reactive dye adsorption has a  
530 marked complicating impact on the models. In the case of reactive dyes, an additional obfuscating  
531 issue arises because of the alkaline conditions that are required to apply the dyes, and the need for  
532 a mathematical treatment that takes into account the influence of alkali-induced ionisation of the  
533 hydroxyl groups in the substrate on dye adsorption (80, 82). Furthermore, as dye hydrolysis always  
534 accompanies dye-fibre reaction, the mechanism of dye hydrolysis has received considerable  
535 attention, in which context, attempts have been made to quantify the efficiency of dye-fibre reaction  
536 in terms of various dyebath parameters.

537

538 The thermodynamic analysis of the adsorption of reactive dyes onto various types of substrate,  
539 including cellulosic materials, has attracted much attention, various adsorption models having been  
540 proposed [eg (83-89)].

541

542 From the foregoing, it is clear that the thermodynamic treatment of the reactive dye/inorganic  
543 electrolyte/cellulosic fibre dyeing system is complicated because of the need to add NaCl or Na<sub>2</sub>SO<sub>4</sub>  
544 to reactive dye dyebaths in order to promote dye uptake. From this it follows that if it were possible  
545 to dye cellulosic fibres using reactive dyes in the absence of added inorganic electrolyte then a  
546 much simpler thermodynamic treatment of the resulting, more straightforward, reactive  
547 dye/cellulosic fibre dyeing system could be advanced that may offer improved agreement between  
548 theoretical mathematical interpretations and experimentally determined dye adsorption data. This is  
549 the subject of a subsequent part of this paper.

550

551 *5.4 kinetics of dyeing*

552 The mechanism by which reactive dyes diffuse within cellulosic fibres prior to dye-fibre reaction can  
553 initially be considered (25) to be comparable to that of direct dyes (2), being described in terms of  
554 the, essentially mechanical, pore model of dye diffusion (90-92); generally, dye diffusion is markedly  
555 influenced by added added inorganic electrolyte. However, in the case of reactive dyes, owing to the  
556 alkaline conditions that are used to expedite dye-fibre covalent reaction, physical adsorption onto  
557 pore walls via intermolecular forces of interaction can also be accompanied by dye fixation, namely,  
558 chemisorption onto ionised hydroxyl groups on the walls. Under such conditions, it seems likely that  
559 in addition to dye diffusion occurring in accordance with the pore model of diffusion, namely, that  
560 diffusion of the dye molecules within water-filled pores is accompanied by simultaneous physical  
561 adsorption onto the pore walls, the diffusing dye molecules can also undergo simultaneous chemical  
562 reaction with ionised hydroxyl groups on the pore walls. As such, the kinetics of dyeing cellulosic  
563 fibres with reactive dyes is very complicated because of the marked heterogeneous nature of the  
564 diffusional process. Consequently, mathematical interpretations of the kinetics of reactive dyeing are  
565 necessarily complex as they must account for both physical diffusion and simultaneous dye-fibre  
566 reaction [eg (22, 93-100)].

567

568 In relatively recent times, the analysis of the kinetics of reactive dye removal from wastewater by  
569 adsorption onto various types of substrate, including cellulosic materials, has attracted attention [eg  
570 (61, 86, 101-104)].

571

572 The foregoing account reveals that the highly complex, multi-faceted diffusional process of reactive  
573 dyes within cellulosic substrates is complicated not simply because of the influence of added  
574 inorganic electrolyte but also due to the fact that dye diffusion involves simultaneous physical  
575 adsorption and chemisorption. Thus, if it were possible to dye cellulosic fibres using reactive dyes in  
576 the absence of added electrolyte perhaps a simpler interpretation of the ensuing reactive dye-  
577 cellulosic fibre diffusion process may result; this will be addressed in a subsequent part of this  
578 paper.

579

580 **6 conclusions**

581 As the adsorption of reactive dyes onto cellulosic fibres in the absence of dye-fibre reaction is  
582 assumed to parallel that of direct dyes, the mechanism by which the dyes are adsorbed is also  
583 presumed to resemble that of direct dyes. As such, the same theories which have been proposed to  
584 explain the promotional effect imparted by added inorganic electrolyte on the uptake of direct dyes  
585 are assumed to apply in the case of reactive dyes. Unfortunately, none of these theories  
586 satisfactorily explains the promotional effect of added electrolyte in terms of the currently accepted  
587 method of describing the mechanism by which reactive dyes are adsorbed on cellulosic fibres,  
588 namely, mathematical interpretations of isothermal equilibrium dye adsorption data that seek to  
589 calculate the thermodynamic standard affinity of reactive dyes on cellulosic substrates,  $-\Delta\mu^\theta$ .

590

591 Furthermore, such interpretations do not describe how dyeing proceeds prior to equilibrium being  
592 achieved, a situation that is relevant to commercial exhaust dyeing processes which do not achieve  
593 equilibrium dye uptake, nor do they adequately account for either the inherently low substantivity  
594 displayed by reactive dyes towards cellulosic fibres in the absence of added inorganic electrolyte  
595 nor the marked ability of added NaCl or Na<sub>2</sub>SO<sub>4</sub> to promote dye uptake.

596

597 In the latter context, it seems probable that the addition of either NaCl or Na<sub>2</sub>SO<sub>4</sub> to a reactive dye  
598 dyebath utilises the inherent propensity of the dyes to aggregate in solution via coplanar  
599 association, and that such electrolyte-induced dye aggregation reduces the solubility of the dye in  
600 the dyebath. However, accepted physico-chemical models of the mechanism by which reactive dyes  
601 are adsorbed on cellulosic fibres are unable to adequately account for the effects of electrolyte-  
602 induced dye self-association in solution and, more significantly, cannot explain the effects of  
603 reduced dye solubility on the dye adsorption process. Thus, an alternative model is required which  
604 can explain the effects of both electrolyte-induced dye self-association and consequent reduced dye  
605 solubility on reactive dye uptake. This is the subject of the next part of this paper.

831

**Highlights**

- the role of inorganic electrolyte in reactive dye application is modelled
- interstitial water is used to show that added electrolyte reduces dye solubility
- added electrolyte promotes dye aggregation
