Supporting Information Placeholder

ABSTRACT: Signal Amplification by Reversible Exchange (SABRE) is used to switchon the latent singlet spin order of para-hydrogen (p-H₂) so that it can hyperpolarize a substrate (sub = nicotinamide, nicotinate, niacin, pyrimidine and pyrazine). The substrate then reacts reversibly with [Pt(OTf)₂(bisdiphenylphosphinopropane)] by displacing OTf to form [Pt(OTf)(sub)(bis-diphenylphosphinopropane)]OTf. The ³¹P NMR signals of these metal complexes prove to be enhanced when the substrate possesses an accessible singlet state or longlived Zeeman polarization. In the case of pyrazine, the corresponding ³¹P signal was 105 \pm 8 times larger than expected, which equated to an 8-hour reduction in total scantime for an equivalent signal to noise ratio under normal acquisition conditions. Hence p-H₂ derived spin order is successfully relayed into a second metal complex via a suitable polarization carrier (sub). When fully developed we expect this route involving a second catalyst to successfully hyperpolarize many classes of substrate that are not amenable to normal SABRE.

The huge sensitivity improvement that is provided by hyperpolarization has significantly extended the scope of magnetic resonance based *in vivo* study.¹⁻³ While several hyperpolarization methods are available to achieve this result, the *para*-hydrogen induced hyperpolarization (PHIP) route is popular because it is fast, simple and relatively low-cost.⁴⁵ Classically PHIP, however, needs to chemically modify the target substrate and this makes it unsuitable for some agents.⁶ This limitation has partially been overcome through the variant of PHIP known as Signal Amplification by Reversible Exchange, termed as SABRE, which no longer relies on active hydrogenation to deliver hyperpolarized material in seconds.⁷ Since its inception, SABRE has become highly successful in delivering huge sensitivity enhancements to a wide range of molecular systems that are clinically relevant.⁸⁻¹¹ It has been shown to work for NMR active nuclei such as ¹H, ¹³C, ¹⁵N, ¹⁹F, ³¹P that feature in substances such as nicotinamide, nicotinate, pyridazine, diazirine and imidazole and achieves net polarization levels as high as 50% for ¹H and 20% for ¹⁵N.^{10, 12-15} Recently, SABRE has been combined with long-lived states such that the hyperpolarized signals it creates remain visible for up to 30 minutes.¹⁶⁻²¹ This exciting development reflects one route to overcome the normal relaxation time scale of NMR which limits many methods. Such advancements are beginning to feature in human metabolomics where the creation of tools for the diagnosis of disease is possible.¹⁻³

Despite the general success of the SABRE hyperpolarization technique, the signal enhancements achieved by this process are currently limited to resonances that originate in ligands which were previously bound to the polarization transfer catalyst (M_1). Although, several types of spin systemhave been shown to perform well with SABRE there is a need to make this approach both robust and more generally applicable. In this study, we show how it is possible to sensitize a second metal complex (M_2 - S_1) via the *relay* of hyperpolarization from substrate (S_1) in a process we term SABRE-*Relay*. Given that M_2 - S_1 no longer needs to react with H_2 , and that with development it could contain labile ligands, we expect this approach to widen the range of substrates which can be hyperpolarized by this type of approach. Scheme 1 illustrates the basis of this effect.

Scheme 1: Schematic depiction of the SABRE-Relay; substrate S_1 binds reversibly alongside p-H₂ to metal complex M_1 and becomes hyperpolarized. S_1 then binds reversibly to M_2 -S₁ and polarization is relayed into its ³¹P response.

The singlet state concept iscentral to the SABRE process. In a pair of coupled spin-1/2 nuclei (e.g. H_2), the term singlet state relates to their antisymmetric spin eigenstate.²² The PHIP concept⁵ then harnesses this singlet state to facilitate enhanced NMR detection. Remarkably in 2004, it was shown by Levitt and coworkers that such singlet spin order can be created by suitable radio frequency (*r.f.*) pulses in many ordinary molecules and the resulting nuclear spin lifetime can extend beyond the more usual T_1 boundary.²³ The long-lived nature of these singlet states can be traced back to the fact that they are immune to one of the major relaxation causing mechanisms, the intra-pair dipole-dipole pro-

cess.²² Long-lived singlet states (LLS) are now being used for hyperpolarization storage, to obtain molecular structure information, and to follow slow-molecular processes.²⁴⁻²⁸ Warren and co-workers devebped a related technique to access LLS in chemically equivalent spin systems by exploiting magnetic inequivalence.²⁹³⁰ In previous work, it has been shown that SABRE derived hyperpolarized LLS can be formed and accessed for several minutes after storing either in high or low-magnetic felds.¹⁸⁻²¹

Scheme 2: Identities of S₁ used in this SABRE-Relay study.

In these experiments, SABRE is first used to hyperpolarize the exchangeable substrate S_1 of Scheme 2 via its scalar-coupling framework. When these are two-spinsubstrates, the hyperpolarization is associated with both Zeeman and singlet spin order as detailed in Scheme 3. Alternatively, the resulting Zeeman polarization can be turned into singlet spin order via r.f. excitation as detailed.¹⁶⁻²¹

S₁ is binding reversibly to **M**₂-**S**₁ throughout this process according to Scheme 3. If **S**₁ were to have singlet spin order and its symmetry were to be broken through the *J*-coupling network of M_2 -**S**₁, its latent polarization should be unlocked and transferred further, in this case into ³¹P.³¹ This strategy reflects the relayed transfer of polarization from *p*-H₂ into a second agent that never actually comes into contact with H₂ and hence the key requirement is that hyperpolarized **S**₁ has along lifetime. This process is depicted in Scheme 3 for [Pt(S₁)₂(dppm)](OTf)₂ (**M**₂**S**₁). Here, **M**₂-**S**₁ rapidly forms from [Pt(OTf)₂(dppm)], where the bidentate phosphine controls the lability of the triflate (OTf) and the potential for any substrate (**S**₁) to bind (see supporting information section S3 and S4 for more details).

Scheme 3: Precatalyst [IrCl(IMes)(COD)] (M₁) is transformed into [Ir(H)₂(IMes)(S₁)₃]Cl (M₁-S₁) by adding *para*hydrogen (*p*-H₂) gas and substrate S₁. S₁ then gains hyperpolarized Zeeman and singlet spin order via polarization transfer from *p*-H₂ depending on its identity. In a second step, the ³¹P response of M₂-S₁ becomes hyperpolarized.

For context, it has been shown experimentally that the addition of p-H₂ leads to sensitization of the ³¹P signature of Ru(H)₂(dppp)(PPh₃)(CO). This effect was explained theoretically on the basis of the coherent evolution of the zero quantum (ZQ) coherence associated with the p-H₂ singlet state under¹H-³¹P spin-spin coupling.³²⁻³⁴ Furthermore, the complex Ir(H)₂Cl(PPh₃)₃ has been shown to hyperpolarize its bound ³¹P responses in addition to that of PPh₃ via SABRE.³⁵⁻³⁶In contrast, the transfer of single spin based ¹²⁹Xe hyperpolarization into a second agent has been shown to proceed via the incoherent spin polarizationinduced nuclear Overhauser effect (SPINOE).³⁷⁻³⁸ There is also the possibility of coherent Zæman order transfer.³⁹⁻⁴⁰ Hence there are several well defined pathways for hyperpolarization transfer between diamagnetic materials that might operate here.

In this section, we demonstrate the experimental viability of SABRE-Relay. We employ the efficient SABRE precursor [IrCl(IMes)(COD)] (M₁) in all cases. Standard SABRE methods are used to polarize the carrier substrates (S_1) of Scheme 3 in the presence of M_1 . Platinum based M_2 contains bisdiphenylphosphinopropane bis-(dppp), diphenylphosphinomethane (dppm) and bisdiphenylphospinoethane (dppe) and a pair of weakly bound triflate ligands. Synthetic details for the formation of M2, and its reactions to form M2-S1 can be found in the supporting information (Section S3 and S4). Samples were prepared in deuteratedmethanol and contained a 1:1 ratio of M_1 and M_2 , with each having a concentration of 5 mM and substrate loading (S_1) of 50 mM. These solutions were then degassed prior to activation with p-H₂. This led to the formation of $[Ir(H)_2(IMes)(S_1)_3]Cl$. Subsequently, SABRE transfer was undertaken at a range of magnetic mixing fields and a series of ¹H and ³¹P NMR measurements made according to the process detailed in Figure 1. After bubbling with p-H₂ at two different magnetic fields, the solution was then transferred into the magnet for NMR measurement which took place after the application of simultaneous 90° pulses to both channels. The magnetic field cycling illustrated is needed to optimally polarize the corresponding ¹H and ³¹P responses of S_1 and M_2 - S_1 respectively and relates to ¹H¹⁵N transfer as exemplified by Theis et al.¹⁶ The formation of a singlet state within the carrier substrate (S_1) was realized either naturally (prot ∞ ol-1: low-field hyperpolarization) or by a suitable r.f. based magnetization-to-singlet (M2S) pulse sequence (protocol-2).²³ We note that hyperpolarized Zeeman derived spin order remains present when the sample enters the high field magnet for observation because the SABRE process is on-going.

In the first measurement, S_1 was H_1 -nicotinamide S_{1a} of Scheme 3. The resulting ¹H NMR signals for S_{1a} showed a 370 \pm 20-fold Zeeman based signal enhancement after SABRE (see Table 1) at 6 mT but no ³¹P NMR signal was detected for M₂-S_{1a} after rapid transfer into the high-field spectrometer for observation according to protocol 1. In this case, S_{1a} contains a single proton and hence there is no possibility to create singlet order in S_{ta} alone. A further control experiment was performed without p- H_2^{a} and again no ³¹PNMR signal was seen for M_2 - S_{1a} in a single scan measurement, although its formation was confirmed after appropriate signal averaging. Hence, we conclude that the presence of M_2 and M_2 -S_{1a} does not stop SABRE from operating with M_{I} , and that substrate S_{1a} is unable to relay polarization into M_{2} - S_{1a} . Furthermore, we note that M_2 - S_1 is not hyperpolarized as a consequence of the p-H₂ that is in solution. We interpret these results to suggest that any single spin Zeeman derived hyperpolarization or SPINOE transfer is at best weak and note that the short ¹H-relaxation times might account for this.⁴¹

Figure 1. Experimentalscheme for SABRE-Relay, showing timings, magnetic field variance and *r.f.* sequence. First the sampleis mix ed with enriched *p*-H₂ at low magnetic field (~6 mT and ~1-10 μ T) for the durations of $\tau_{\rm LF1}$ and $\tau_{\rm LF2}$ before moving to high field ($\tau_{\rm tr}$) for NMR observation. A simultaneous 90° pulse is applied to ¹H and ³¹P prior to acquiring the ³¹P signal with ¹H decoupling (protocol 1). In a second variant, protocol 2, an M2S sequence²³ is applied between $\tau_{\rm LF1}$ and $\tau_{\rm LF2}$.

We then examined the three variants of nicotinamide, S_{1b} , S_{1c} and S_{1d} where we have previously demonstrated that both Zeeman and singlet order can be created in their aromatic protons via SABRE and r.f. driven transfer.¹⁹ All three of these substrates now yield SABRE hyperpolarized ¹H NMR signals with signal gains lying between 200 and 250-fold per proton for their Zeeman polarizations after transfer at 6 mT when observed at 9.4 T. A ³¹P NMR measurement was then made on each sample according to protocol 1 of Figure 1. This resulted in the detection of a ³¹P signal for both of the inequivalent phosphorus centers in the corresponding M_2 -S₁ complexes. These signals were enhanced over their thermally polarized levels by 65, 88 and 32-fold respectively. The corresponding enhancement values were determined by comparison with signal averaged ³¹P NMR spectra of M_2 -S₁. When protocol 2 for S_{1b} and S_{1c} was applied, the resulting ³¹P signal gains were 42-fold and 50-fold respectively. It islikely that the weaker ³¹P signal gains result from the longer experiment time. We note that the similarity in the single proton relaxation times of S_{1a} and S_{1b} suggests again that any SPINOE or Zeeman derived contribution would be weak.

These observations can be explained if the singlet symmetry of S_1 is broken upon binding and polarization transfer into the ${}^{31}P$ nuclei of $M_2.S_1$ occurs. In the case of S_{1b} a 5-bond ${}^{1}H^{-31}P$ coupling would be involved in this step whilst for S_{1c} and S_{1d} larger four bond couplings would operate. The reduced enhancement level seen with S_{1d} is predicted to reflect the rapid relaxation of its singlet state in the reaction mixture (Table 1). The corresponding values for S_{1b} and S_{1c} are longer but still smaller than their 34 s and 39 s values in the absence of the catalyst. Hencein accordance with this hypothesis, the presence of M_1 and M_2 - S_1 is seen to impact directly on the T_{LLS} lifetimes. Figure 2 shows the corresponding ${}^{31}P$ NMR traces after the 1-shot SABRE-Relay process with S_{1a} S_{1b} , S_{1c} , and S_{1d} to illustrate this behavior.

Figure 2. Single scan ${}^{31}P{}^{1}H$ NMR spectra associated with (A) M_2 - S_{1a} ; (B) M_2 - S_{1b} ; (C) M_2 - S_{1c} ; (D) M_2 - S_{1d} using SABRE-Relay protocol 1 of Fig. 1.

Table 1. ¹H and ³¹P signal enhancements and lifetimes determined for free S_1 and the two ³¹P signals of M_2 - S_1 achieved with a 50 mM loading of S_1 at 9.4 T recorded using protocol 1.

*protocol2

An improvement in the level of ³¹P NMR signal gain, from 32fold to 56-fold is observed with M_2 - S_{1d} when protocol 2 is used. This again suggests the involvement of a coherent spin order transfer mechanism leading to the hyperpolarized ³¹P NMR signal. Similar experimental strategies were then employed to examine related S_{1e} and S_{1f} . In the case of S_{1e} , while very strong ¹H SABRE results the relayed ³¹P signal gains are lower. This is again likely to be a consequence of their relatively short magnetic state lifetimes.

When substrates S_{1g} (pyrimidine) and S_{1h} (pyrazine) were examined, the observed ³¹P NMR signal enhancements increased to over 100-fold (Table 1). Figure 3 shows the corresponding ³¹P NMR spectra of M_2 - S_{1g} and M_2 - S_{1h} when a 50 mM substrate concentration was employed with M_2 at the 5 mM level. This improvement confirms that the identity and properties of S_1 are important in controlling the visibility of M_2 - S_1 . In these two cases, slow exchange is predicted which confirms that catalyst life-time plays a role in this process.

Figure 3. ³¹P{¹H}NMR spectra associated with M_2 -S_{1g} and M_2 -S_{1h} (structures above NMR spectrum) that form from M_2 and S_{1g} or S_{1h} respectively. Inboth cases, the upper ³¹P NMR spectrum is the control which involved 128 transients, whilst lower NMR spectrum was acquired by the SABRE-Relay through process 1 and associated with a single detection pulse according to Figure 2.

In a final refinement, we studied two other platinum metal complexes - $[Pt(OTf)_2(dppm)]$ and $[Pt(OTf)_2(dppe)]$, and similar SABRE-Relay experiments were performed. While ³¹P-signal enhancements were again observed, they were significantly lower than those seen for the dppp complex. The decrease in enhancement factor reflects a combination of residence time and relaxation effects. We are currently studying these effects in greater detail. Nonetheless, the associated signal enhancements confirm that several metal complexes are active for SABRE-Relay. The experimental details, and results for $[Pt(OTf)_2(dppm)]$ and $[Pt(OTf)_2(dppe)]$ are presented in supporting information sections S3-S5.

In summary, we have demonstrated how SABRE can be cascaded into a second metal complex via a coherent transfer pathway involving a series of hyperpolarized substrates. This involved the detection of enhanced ³¹P NMR responses in a metal complex which does not interact directly with H. Hence, we have presented a route to overcome one of the key SABRE limitations, associated with p-H₂ being the singlet carrier. N-heterocycles can bind to many metal complexes which in turn may contain other labile ligands. We expect to be able to use SABRE-Relay to enhance new classes of agents that are not amenable to the traditional SABRE hyperpolarization route. The mechanism of transfer is likely to be based on a coherent spin order route such as that involved in singlet state evolution via S1 which is directly analogous to the original SABRE concept. However, we note that this process simply involves propagation of the low-field created ZQ coherence but other routes involving coherent polarization transfer from Zeeman order under these low field conditions may contribute and we are now seeking to differentiate their contributions.^{40, 42}Regardless of the pathway, we take advantage here of what would be expected to be relatively large³¹P couplings to propagate these effects and therefore expect an efficient second step. Given the interest in hyperpolarized MRI the potential of this approach to improve magnetic resonance sensitivity may be significant and we are currently working on the optimization of this technique.
