SUPPLEMENTARY INFORMATION

Towards a bioelectronic computer: A theoretical study of a multi-layer biomolecular computing system that can process electronic inputs

Katherine E. Dunn*, Martin A. Trefzer, Steven Johnson and Andy M. Tyrrell

Department of Electronic Engineering, University of York, Heslington, York, YO10 5DD, UK

Correspondence and requests for materials should be addressed to K.E.D. (k.dunn@ed.ac.uk)

*Present address: School of Engineering, Institute for Bioengineering, University of Edinburgh, Edinburgh, EH9 3DW

Supplementary Discussion 1: Experimental considerations

Our proposed system is modular, and has several layers of information-processing capacity. To test our system experimentally, it would be necessary to test each layer individually and in combination with other layers. The complexity of the tests (in terms of the number of layers involved) would gradually increase until all layers were operating together. As far as possible, our system is based on components that have previously been well-characterized by others.

The operation of individual DNA machines or units within the system could be tested using a scheme in which fluorophore emission is modulated by a quencher or fluorophores interact through FRET. It would not be necessary to perform microscopy, as single-molecule level information is not required. Bulk measurements made using a fluorimeter or equivalent

apparatus would suffice. Polyacrylamide gel electrophoresis could also be used to characterize some aspects of the DNA circuitry.

To successfully integrate all layers, it would be necessary to identify a medium that could accommodate all processes. The solution selected should have limited buffering capacity, to enable the pH to be changed electrochemically. The concentration of sodium and/or magnesium ions would need to be at the usual level required for DNA hybridization (mM).

Supplementary Discussion 2: How long does each cycle take?

The production of OB takes 125 minutes (including the period for which the switch is open and a subsequent equilibration period). The thresholding stage takes 100 minutes and results in production of some combination of A-D. The operation of the logic gates takes 250 minutes and the finite state machine takes 100 minutes to change state. The total length of each cycle is therefore: $125+100+250+100=575$ minutes = 9 hours and 35 minutes.

Supplementary Methods

This part of the document provides the MATLAB routines used to perform the simulations described in the paper. The standard MATLAB colour code is used. Underlined code can be edited to change the parameters of the system.

1. Simulating the Zhang catalytic cycle with a voltage-activated pH sensitive switch as a catalyst

(a) MATLAB routine – for specific individual concentrations

4. Modelling the finite state machine

MATLAB routine.

```
%Katherine Dunn
%Simulation of a DNA finite state machine changing state.
%This code takes one initial state and one condition and shows
how the
%machine will transition to the final state.
%The states and conditions do not have to be 'pure', so this is
really a
%simulation of an ensemble of machines, some of which may be in
the wrong state.
%Each 'pure' state corresponds to a single output colour that
could be aligned
%with fluorescence of e.g. Alexa Fluor 568 (red), 488 (green)
and 350 (blue).
