Abstract

Argillites that strongly luminesce under UV radiation were detected in the Bazhenov Shale Formation (BSF) of the West Siberian Basin during routine core examination and found to be persistent over a wide lateral area. The mineralogy and fabric of these luminescent layers were characterized by optical and fluorescence microscopy, SEM, TEM, XRD and IR methods. Optical and fluorescence microscopy showed that the luminescent layers were to a large extent derived from volcanic ash falls and could be described as meta-tuffites, although normal detrital sedimentation continued at the same time. The layers have a thickness of several mm to a maximum of 3-4cm and can be defined as a clay-rich regional horizons. XRD showed that two principal clay minerals were present, namely a kaolinite, possibly with some dickite stacking, (kaolin-rich) and a mixed-layer illite-smectite (I/S) with R1 to R2 ordering similar to that found in K-bentonite. Total organic matter in the luminescent layers is much lower than that in the enclosing BSF clayey-silty siliceous sediments above and below as shown by pyrolytic analyses. Evidence is presented that the luminescent characteristic of the argillites is related to their clay mineralogy, specifically to their content

1 of kaolin minerals, although a contribution from nitrogenous organic matter cannot be
2 entirely discounted. In some ways the luminescent argillites can be compared with bentonites
3 associated with ash transformations or with tonsteins in coal beds, which are also derived
4 from volcanic ash falls and contain highly crystalline kaolinite. However, tonsteins originate
5 at or near land surface whereas the argillites were apparently formed in the deep ocean. But
6 just as tonsteins can be used for detailed stratigraphic studies and are valuable in the context
7 of coal exploration, so may the luminescent argillites prove to be significant both
8 stratigraphically and in the search for economic hydrocarbon deposits, bearing in mind that
9 their clay mineralogy may be sensitive to temperature and depth of burial and related to their
10 placement in the oil and gas window.

31 **1. Introduction**

32
33

34 The Bazhenov Shale Formation (BSF) occurs over a million square km in west Siberia and is
35 widely accepted as having acted as the principal source for the hydrocarbon resources of the
36 West Siberian Basin (Ulmishek, 2003). This basin formed a huge sedimentary depocentre
37 extending from the southern part of west Siberia northwards to the Kara Sea (Fig. 3) during
38 Mesozoic to Cenozoic times, and overlies a basement complex of tectonically altered,
39 metamorphosed rocks of Palaeozoic age which formed part of the Pangea super continent.
40 The BSF is of Upper Jurassic (Volgian) age and its detailed composition and genesis has
41 been studied by many Russian researchers from 1960 onwards and more recently by
42 Kontorovich et al. (1998), Zanin et al. (1999), Eder et al. (2003) and Zanin et al. (2003). The
43 mineralogy and geochemistry of the BSF were characterized by Zanin et al. (2008) who
44 concluded that it was made up of three main rock types, namely (a) clayey-silty siliceous
45

1 rocks and cherts containing high organic matter and dark-brown in color, (b) argillites, where
2 the clay content exceeds 40% containing low organic matter and of a lighter brown color
3
4 (Fig. 1) and (c) rocks described as “anomalous” and which could be of a clayey, silty or
5
6 sandy nature. Argillites are frequently found inter-bedded with the clayey-silty siliceous
7
8 rocks (Zanin et al., 2008). Dolomitic rocks also occur sporadically within the BSF sequence.
9
10 Based on mineralogical and chemical criteria the depositional environment of the most
11
12 widely occurring clayey-siliceous rocks is thought to have been characterized by extremely
13
14 reducing anoxic conditions, while the argillites are considered to represent distal turbidites
15
16 that were deposited in dysoxic to suboxic conditions. The anomalous clayey, silty, sandy
17
18 rocks were considered to have been deposited in channels under oxic conditions.
19
20
21
22
23
24

25 The present study was prompted by the observation during routine core examination of the
26
27 BSF highly luminescent under UV light occurred at certain points in the sequence of siliceous
28
29 silty shales that make up the majority of the BSF (Fig. 2). These luminescent layers appear to
30
31 be so laterally extensive that they could possibly be of use as stratigraphic markers. Clearly,
32
33 however, these layers require to be investigated in detail with regard to their nature and origin
34
35 if their value in correlation studies as well as in other issues is to be established with
36
37 confidence. The objective of the present paper, therefore, is to characterize the mineralogical
38
39 and chemical nature of these luminescent layers, to determine the likely origin of the
40
41 luminescence of these layers, and to assess whether there is a rational basis for the possible
42
43 use of these layers as stratigraphic markers in the BSF as a whole.

51 **2. Materials**

52 **2.1. Geological Setting**

53
54
55 The BSF is usually 20 to 40 m in thickness, although in certain localities thicknesses of up to
56
57 60 m have been recorded. The shales are black or dark-brown in colour and are high in
58
59
60
61
62
63
64
65

organic matter, with total content of C_{org} in the range of 2 to >11% with an average of 4%.

The chemical composition of the organic matter corresponds to kerogen type II (Goncharov et al., 2014). This indicates a high potential for hydrocarbon occurrence that could be explored for oil and gas. The essentially detrital nature of the Bazhenov Shales is evident from thin sections, although the role of diagenesis as a determinant of the overall shale mineralogy is also important as shown by Shaldybin et al. (2017).

Sedimentation rates for the clayey-silty siliceous rocks of the BSF are thought to have been extremely low especially within the deepest parts of the sedimentary basin. Thus, Zanin et al. (2008) calculated a rate of 0.4 to 0.5 cm per 1000 years on the basis of the average thickness of the BSF and the time during which the formation was deposited, a rate generally consistent with bioclastic sedimentation in deep water environments (Einsele, 2000; Jenkyns and Clayton, 1986). Sedimentation rates for the argillites, are considered to have been very much faster, bearing in mind their origin as distal turbidites.

The BSF is thought to have originated in an isolated, marine basin analogous to the Black Sea where reducing conditions and intensive hydrogen sulfide generation preserved abundant organic matter (Vyssotski et al., 2006). The salinity of the Bazhenov Sea as determined by the B/Ga ratios corresponded to normal marine conditions for clayey-silty siliceous rocks and a more brackish environment for the argillites (Zanin et al., 2008). However, there have been a variety of opinions concerning the depth of the Bazhenov Sea (Zanin et al., 2008 and references therein). Early studies favoured a shallow depth (~10 m) but this was not supported by later research which pointed to much greater palaeo-water depths. Thus, Vyssotski et al. (2006) suggested that at certain stages of development the Bazhenov Sea was 1200 m deep in its central part, although Zanin et al. (2008) conclude that optimum depths of 500 m or deeper are more likely. Beginning in the Upper Oxfordian, the sediment of the

1 Bazhenov Sea is thought to have been deposited over a period of 8 to 10 million years. This
2 deep-water basin was gradually filled in Neocomian times by a succession of deltaic clastic
3 wedges (clinoforms) prograding towards the west and derived from erosion of the Siberian
4 platform (Ulmishek, 2003). Shallow marine sedimentation, largely of siliciclastic material,
5 continued during Lower Cretaceous times, building up to a thickness of 1.4 to 1.5 km. With
6 continuing sedimentation the total thickness of the Cretaceous and Cenozoic sediments
7 overlying the BSF approaches 2.75 km.

18 2.2. Sampling

19
20
21 Core samples were obtained from 10 wells within the Bazhenov Shale Formation. Figure 3
22 shows the area covered by these wells, extending for 500km from east to west and 400km
23 from north to south. Samples were obtained from cores taken at depths 2200 to 2450 meters
24 that represent the organic-rich Bazhenov Shale. Investigations were concentrated on the
25 luminescent layers but pyrolysis data were also obtained for BSF layers rich in organic matter
26 1-2 cm above and below luminescent layers (samples A and C, Table 4).

38 During routine core studies highly luminescent layers were observed under UV light. These
39 luminescent layers and laminations usually have a thickness of 2-3 cm, sometimes reaching
40 5-6 cm, and appear to correspond to clay-rich argillites rather than the clayey-silty siliceous
41 sediments that form the bulk of the BSF. Samples were taken of luminescent argillite material
42 and associated clayey-silty siliceous shales from cores recovered from 10 separate wells in
43 the central part of the BSF. Wells P-1, S-2, L-3, K-4 and V-5 are situated in the central part
44 of the West Siberia Basin traversing from west to east. Wells R-6, E-7, G-8, M-10 and D-9
45 cover the south-east margin of the basin. In well D-9 we have found two layers with
46 luminescence properties: an upper thin layer with a thickness of 5-10 mm and a lower layer
47 composed of a series of numerous thin layers totally a thickness of about 5-6 cm (Fig. 3).

6 7 **3. Methods**

8 9 **3.1. Optical Microscopy**

10 Geological samples were prepared into standard thin sections. Sections were polished down
11 to 1µm with diamond finished and carbon coated (Cressington 108 carbon sputtering unit)
12 with a 20nm thickness. Thin sections of core samples from both the clayey-silty siliceous
13 rocks and the luminescent layers were studied by optical microscopy using an Olympus BX-
14 51 polarizing microscope. The samples were studied in plane polarized light under crossed
15 polars so as to characterize the mineralogy (both authigenic and detrital minerals), as well as
16 the organic and inorganic fine-grained phases, paying particular attention to textural and
17 structural features.

3.4. Transmission Electron Microscopy

1
2
3
4 Fractionated clay samples (<2 μ m) of the luminescent layers were examined by TEM.
5
6 Samples were prepared by dispersing in methanol and in distilled water and pipetting single
7
8 drops of the suspension onto copper TEM grids with holey carbon supports. The samples
9
10 were examined using bright field imaging at 200kV using an FEI Tecnai TF20 field emission
11
12 TEM/STEM. Energy dispersive X-ray (EDX) spectra were obtained using an Oxford
13
14 Instruments XMax80 Silicon Drift Detector and processed using Aztec software, whilst
15
16 selected area electron diffraction patterns were recorded using a Gatan Orius SC600A CCD
17
18 camera.
19
20
21
22
23

3.5. X-Ray Diffraction

24
25
26
27
28 The mineral composition of the luminescent layer samples was investigated by X-ray
29
30 diffraction methods using a Rigaku Ultima IV powder diffractometer. Bulk samples were
31
32 prepared by crushing selected core material followed by gentle grinding in a mortar with
33
34 further grinding in McCrone mill to a particle size less than approximately 10 μ m. Randomly
35
36 oriented powder samples for XRD analysis were prepared following spray-drying according
37
38 to the recommendation of Hillier (2003). Clay fractions (<2 μ m) were collected from aqueous
39
40 dispersions following treatment with hydrogen peroxide and sodium hypochlorite to remove
41
42 organic matter. This treatment proved to be ineffective and more complete dispersion was
43
44 only achieved following treatment with domestic detergent. Oriented samples were prepared
45
46 by drying the dispersed clay on to glass slides. These samples were then examined by XRD
47
48 in air-dried and ethylene glycol solvated states and after heating up to 550°C due to 2 hours.
49
50 The XRD-patterns were measured using a Cu anode at 40 kV and 30 mA. Quantitative
51
52 mineralogical analyses for the bulk samples were performed by Rietveld analysis (Bish and
53
54 Post, 1993) using PDXL and Siroquant software (Taylor, 1991).

3.6. Fourier Transform Infra-Red (FTIR) Spectroscopy

1
2
3
4 1mg of each of the treated and separated clay fractions of the luminescent layers was
5
6 incorporated in a potassium bromide pressed disc and Infrared (IR) spectra recorded over the
7
8 frequency range $4000-400\text{cm}^{-1}$ using a Nicolet Magna-IR 550 (Thermo Scientific) Fourier
9
10 Transform Infrared Spectrometer. The IR spectra were compared with reference spectra
11
12 recorded from standard minerals.
13
14

3.7. Trace Element and Selected Major Element Analysis

15
16
17
18
19
20 The concentrations of 29 elements for 6 representative luminescent layer samples were
21
22 determined using instrumental neutron-activation analysis (INAA) at the Nuclear
23
24 Geochemical Laboratory of the Department of Geology of Tomsk Polytechnic University in
25
26 Russia. The same 6 samples were additionally analyzed by ICP-MS for 53 trace elements.
27
28 The samples were ground to $\leq 0.071\text{mm}$ and dissolved in a mixture of concentrated nitric,
29
30 hydrofluoric, and hydrochloric acids. The ICP-MS analysis was done on the ELAN DRC-E
31
32 equipment at the Chemical-Analytical Center “Plazma”, Tomsk. Determinations were made
33
34 of the concentrations of Nb, Y, Zr, Ti, as well as some other elements, which are important
35
36 for the identification of the initial magma composition from which volcanic ash is derived.
37
38
39
40
41
42

3.8. Pyrolysis Analysis

43
44
45
46
47 Pyrolytic analyses of samples of bulk luminescent rock samples were performed according to
48
49 the procedures of RockEval 6 so as to enable further characterization of the organic matter
50
51 fraction (Espitalie et al., 1985).
52
53

3.9. CHSN Analysis

54
55
56
57
58
59
60
61
62
63
64
65

1 The total percentages of carbon, hydrogen, nitrogen and sulphur were determined using a
2 CHNS analyzer (Thermo Flash EA 2000, Thermo Fisher Scientific, Italy). For the CHNS
3 analysis, freeze-dried and crushed samples were weighed (2–4 mg) and mixed with an
4 oxidizer (vanadium pentoxide) in a tin capsule, which was then heated in a reactor at 950°C.
5
6 The reaction of oxygen with the tin capsule at high temperature leads to raising the
7 temperature in reactor up to about 1800 °C. At high temperature both organic and inorganic
8 substances are converted into CO₂, H₂O, SO₂ and NO₂ (NO₂ is further reduced in the reactor),
9 which are separated in a chromatographic column and detected by a thermal conductivity
10 detector (TCD). The analyzer was calibrated using various samples of standard organic
11 substances for quantitative determination of C, H, S and N. All samples were taken from
12 luminescent argillite layers.

27 **4. Results**

28 Routine study of well core material recovered from the sediments of the Bazhenov suite is
29 normally carried out by photographing the core under ultra-violet radiation (UV). This
30 procedure aims to identify the presence of hydrocarbons (HC) that are known to luminesce
31 under UV radiation. Carbonates also often luminesce under UV radiation in core material in
32 different colors from bright yellow to bright red. On many occasions, however, the nature of
33 the luminescence in the BSF is unknown and cannot be related to either carbonate layers or
34 the presence of hydrocarbons. Thus, under UV radiation intensely luminescent layers were
35 observed within the BSF both as single layers and as thin multiple laminations (up to a
36 millimeter in thickness) within a small interval (Fig. 2).
37

46
47
48
49
50
51
52

53 **4.1. Optical Microscopy**

54 In general, the BSF is mostly made up of clayey-silty siliceous rocks, which may be regarded
55 as silicites or radiolarites, containing rare layers of carbonate-rich material. Petrographically,
56
57
58
59
60
61
62
63
64
65

1 these rocks consist of fine micro-grain siliceous aggregates (35-40%), clay material (30-
2 35%), with terrigenous detrital silty admixtures (up to 10-15%). The detrital admixture is
3 distributed irregularly, forming fine silty lenses and powdery layers, consisting of quartz and
4 feldspar detritus. Authigenic minerals include sulphide (pyrite and marcasite, sometimes up
5 to 7-10%) and isolated grains of calcite, which are irregularly distributed within the rock.
6
7 Organic matter (kerogen) is present in both concentrated form and dispersed as elongated and
8 thread-like inclusions that form discrete red-brown and ginger-coloured layers. These
9 formations are distributed regularly or in a layered way and colour the rock in shades of dark
10 brown in polished sections, indicating their organic-rich nature.
11
12
13
14
15
16
17
18
19
20
21
22

23 In contrast, the luminescent layers tend to be much lighter in colour in polished sections
24 suggesting an organic-poor nature (Fig. 1). Moreover, optical microscopy showed that the
25 luminescent layers had a completely different fabric and micro-structure from that of the
26 general sequence. Thin sections were made of the different components making up a complex
27 of thick and thin luminescent layers. All layers showed a fabric consistent with that of poorly
28 sorted, volcanic ash particles accompanied by a simultaneous accumulation of normal
29 sedimentary material (Fig. 4). The meta-tuffites could possibly be related to the volcanic
30 activity of Late Jurassic age that has recently been shown to have occurred in the Shadoron
31 area of South East Transbaikalia (Stupak et al., 2016). For the most part, the luminescent
32 layers are interpreted as consisting of meta-tuffites and could be regarded as a K-bentonite or
33 a kaolin rich K-bentonite. The main mass of these rocks looks to be made up of devitrified
34 glass in flattened and sinuous aggregates that could not possibly result from epiclastic
35 sedimentary processes. The spatial distribution of the volcanic detritus corresponds to the
36 structure of “plate stack” and shows that this rock debris has a flattened shape in cross-
37 section but is isometric when observed perpendicular to the stratification. Quartz crystals are
38 observed within the volcanic detritus, some with sharp angular edges and needle shapes and
39

1 occasional high temperature twins of Dauphiné type. Feldspar crystals are also observed with
2 occasional polysynthetic twins. Dolomitized debris is common in the luminescent layers and
3
4 organic matter is usually low, although some layers have a high OM content.
5
6

7 8 4.2. Fluorescence Microscopy 9

10
11 Observations with the fluorescence microscope showed that the luminescent layers are made
12
13 up of discrete particles of diverse morphologies including rough lozenge-shapes, flattened
14
15 discs and sinuous threads (Fig. 5a). These morphologies are clearly very similar to the meta-
16
17 tuffite particles observed by optical microscopy as illustrated in Figure 4. The contrast
18
19 between the luminescent argillite and the adjacent clayey-silty siliceous rock is vividly
20
21 illustrated by Fig. 5b.
22
23
24
25

26 27 28 4.3. Scanning Electron Microscopy 29 30

31
32 Back-scattered SEM images from polished thin sections of a clay-rich luminescent sample of
33
34 the BSF are shown in Fig. 6. Two morphologically distinct phases are immediately evident.
35
36 The first consists of blocky crystalline aggregates, some 5 to 10 μm in length, which can be
37
38 seen to be delaminating along basal surfaces into units $<2\mu\text{m}$ in thickness. These aggregates
39
40 yield EDS consisting only of Si and Al peaks in about equal intensity and enable their
41
42 identification as a kaolinite. The second phase consists of a continuous mass of clay minerals,
43
44 with boundaries that are a change in texture from the kaolin mineral. EDS shows that this
45
46 material is also aluminous but with significant peaks of K and Mg and is identified as a illite
47
48 and illite-smectite clay minerals (Fig. 6c). Pyrite is certainly authigenic, forming in
49
50 framboidal aggregates in the relatively anoxic environment of the deep marine sediment
51
52
53
54
55
56

57 4.4. Transmission Electron Microscopy 58 59 60 61 62 63 64 65

1 The ostensibly pseudo-fibrous nature of the mixed-layer I/S clay material in the luminescent
2 argillite which is suggested by the SEM micrographs is not confirmed by TEM examination.
3
4 In fact, most of the dispersed particles have an irregular, indeterminate, platy morphology and
5
6 no clearly fibrous particles are to be seen (Fig. 7). However, most of these particles are
7
8 clearly aggregates made up of smaller particles, usually of equally indeterminate
9
10 morphology, although occasional laths and hexagonal kaolinite-like fragments can also be
11
12 seen. Platy particles with curled edges and some fully rolled up laths, which could in
13
14 principle be mistaken for fibrous particles, are also evident. Some aggregates appeared to
15
16 show a substructure of lath-like particles and at the edge of these aggregates a hexagonal
17
18 single crystal electron diffraction patterns were recorded (Fig. 8a and 8b). However, a
19
20 turbostratic-type selected area electron diffraction pattern, typical of smectite aggregates
21
22 where the structural sheets are arranged at random with respect to the electron beam, was
23
24 recorded from aggregates of platy particles (Fig. 9a). Spacings of 4.20 to 4.40Å characteristic
25
26 of a dioctahedral mica mineral were measured from this pattern. This suggests a similar
27
28 random orientation of whatever structural units are making up the platy particle. In Fig. 9b,
29
30 the (00l) and (hk0) d-spacings were measured at 10.3 and 4.40Å respectively, also
31
32 characteristic of mica type mineral. A qualitative EDS analysis of these regions gave the
33
34 following results (in atomic %): Si 18.8%; Al 12.1%; K 1.2%; Mg 1.1%; Ca 0.2%; Fe 0.1%
35
36 and O 66.6%.

47 4.5. X-Ray Diffraction

48
49
50

51 XRD showed that the luminescent argillites are significantly more clay-rich than in the
52
53 normal BSF sequence and that two main types can be distinguished, namely (1) luminescent
54
55 layers rich in kaolinite minerals and (2) luminescent layers also yielding a strong reflection at
56
57 11.3Å which expands to 12.1Å after ethylene glycol treatment signifying a mixed-layer
58
59
60
61
62
63
64
65

1 illite/smectite. Quartz, feldspars, carbonates and sulfides are present as minor phases (Table
2 1). The luminescent argillite layers all have a clay content determined by XRD (Kaolinite +
3 I/S) of between 70 and 80% whereas the host clayey-silty rocks of the Bazhenov Shale have
4 an average clay content of only 22.91% (Zanin et al., 2008). The country rocks of the non-
5 luminescent materials, the main phase of the BSF, are siliceous materials sometimes with
6 anomalous contents of carbonates, mainly dolomite (Compare Tables 1 and 2).
7
8
9
10
11
12
13
14
15

16 Figure 10 shows an XRD pattern of a luminescent layer that is kaolinite-rich. The kaolinite is
17 evidently a well crystalline variety as shown by the sharpness of the diffraction peaks as well
18 as the good resolution of the hkl peaks in the 4.36-4.12Å range. The XRD pattern for dickite
19 shows that the two strongest diagnostic reflections for dickite occur at 3.79 and 3.43Å
20 (Wilson, 2013) but only one of this reflections (3.79Å) has been found. Other hkl reflections
21 correspond with well-crystallized kaolinite and it is concluded that the sample consists
22 mainly of kaolinite, although we do not exclude a combined composition for the kaolin-rich
23 layer consisting of mainly kaolinite with at least some dickite stacking.
24
25
26
27
28
29
30
31
32
33
34
35

36 Figure 11 shows oriented XRD patterns of a luminescent layer with a felted, pseudo-fibrous
37 appearance following air drying, glycolation and heating to 550°C. It is evident that kaolinite
38 is minimal in this sample and that the effect of glycolation is to expand the major peak at
39 about 11.3Å to about 12.1Å, a response normally construed as indicating the presence of
40 smectite interlayers. This interpretation was confirmed by the result of heating to 550°C
41 which brought about a contraction of the main reflection at 11.3Å to about 10.1 Å. It would
42 seem, therefore, that the results can be interpreted as a mixed-layer illite-smectite (I/S) but
43 there were no matching calculated curves illustrated in either random or ordered forms in
44 Reynolds (1980) or in Moore and Reynolds (1997). However, Hong et al. (2016) recorded
45 similar spacings from air-dried and ethylene glycol solvated clay fractions from altered

1 Permo-Triassic volcanic ashes in Guizhou Province, South China, and using the NEWMOD
2 program for Windows (Reynolds and Reynolds, 1996) obtained matching experimental and
3
4 calculated one-dimensional XRD patterns for ordered R3 and R2 I/S structures (~90/10 up to
5
6 75/25). An alternative explanation could be that the I/S mineral consists largely of a simple
7
8 R1 stacking sequence, which is interrupted by discrete sequences of illite layers, rather than a
9
10 complex of R2 and R3 stacking sequence as described by Hong et al. (2016).
11
12
13

14 4.6. Infrared Spectroscopy 15

16
17
18
19 Figure 12a shows an IR spectrum obtained after separation of the clay fraction of a
20
21 luminescent layer from non-clay minerals and organic compounds. The pattern is
22
23 characterized by intense OH-stretching bands in the 3600-3700 cm^{-1} range. The relative
24
25 intensities of these bands match the spectrum for dickite shown by Russell and Fraser (1994)
26
27 more closely than they do that of kaolinite (Fig. 12b and 12c). In particular, in dickite Russell
28
29 and Fraser (1994) recorded a band at 3704 cm^{-1} which they attributed to internal surface OH
30
31 groups, whereas in the luminescent layer clay this band occurs at 3689 cm^{-1} , which is closer,
32
33 although not identical to that yielded by kaolinite. The OH deformation bands occurring at
34
35 936 and 910 cm^{-1} in the luminescent sample are not diagnostic and could be attributed to
36
37 either kaolinite or dickite.
38
39
40
41
42
43

44
45 Also present in the spectrum is a weak absorption band at 1423 cm^{-1} . This could be due to
46
47 carbonate, as calcite is present as a trace constituent in some of the luminescent layers, or to
48
49 the NH_4^+ cation which could be located in the interlayer space of the mixed-layer I/S phase.
50
51 Heating experiments favour the latter interpretation, as calcite decomposes to release CO_2 on
52
53 heating to ~ 850 to 900°C while the interlayer NH_4 decomposes to NH_3 following heating at
54
55 530-570°C (Higashi, 1982). As can be seen from Fig. 18 the absorption band at 1432 cm^{-1}
56
57
58
59 disappears from the spectrum between 500 and 700°C.
60
61
62
63
64
65

4.7. Trace Element and Selected Major Element Analysis

1
2
3
4 The trace element chemical composition of the luminescent argillites is as well as the clayey-
5
6 silty siliceous rocks of the Bazhenov Shale similar to the average composition of sedimentary
7
8 rocks (Grigor'ev, 2003, Rikhvanov et al., 2015), but the samples are also characterized by
9
10 some specific peculiarities. Their most noticeable feature is a high content of the radioactive
11
12 elements uranium and thorium (Table 3), which is similar to the content of the Bazhenov
13
14 suite. These uranium anomalies were studied by Baturin (1975) and Kochenov and Rasulova
15
16 (1978) who showed, using examples from modern marine basins, the key role of organic
17
18 matter in uranium accumulation. A high content of As and Se is also indicative of the
19
20 supergenetic nature of uranium accumulation, which often accompanies hydrogenous
21
22 deposits of uranium in a reducing environment. According to Spears (2017), the same
23
24 assemblage (As, Se, Sb, Cu, Pb, Tl, Cd and U) is typical for marine shales and marine-
25
26 influenced coals. High thorium content in the hypergenetic zone of marine sediments is
27
28 primarily indicative of mechanical accumulations in the coastal zone of monazite placers and
29
30 other stable thorium-bearing heavy accessory minerals. Leaching of mobile elements from
31
32 marine suspension and the relatively slight increases in the concentrations of the other slowly
33
34 moving hydrolysable elements during hypergenesis could explain their insignificant
35
36 accumulation and a composition that does not differ much from bulk sedimentary rock
37
38 values. Moreover, the luminescent layers do not show contrasting anomalies of these
39
40 elements, indicating sedimentation of material that was primarily enriched with thorium. This
41
42 material could have been derived from some initially thorium-enriched crusts of weathering
43
44 or from thorium-enriched volcanogenic pyroclastic materials. Here, a volcanogenic source
45
46 appears more likely source, as thorium-bearing horizons are found extending along hundreds
47
48 of kilometers at a small but constant thickness. This mode of substance distribution is
49
50 consistent with catastrophic phenomena such as simultaneous ash falls over a large territory.
51
52
53
54
55
56
57

59
60
61
62
63
64
65

1 The content of individual REE in luminescent layers and the course of their normalized
2 distribution curves confirm a clastogenic mechanism of their accumulation. The
3 concentration of light REEs is close to their content in volcanic rocks of acidic and
4 intermediate igneous nature, but for the heavy REEs is significantly lower. One possible
5 reason is loss of heavy REEs during sediment leaching. It is known that heavy REEs readily
6 form complexes with organic ligands and could thus be extracted from the luminescent
7 layers. The low Eu content indicates either an intermediate or weakly-acidic composition of
8 the initial pyroclastics, corresponding to andesites, dacites, rhyodacites, etc. and this is also
9 consistent with the low content of Fe, Co, Ni.

23 4.8. Pyrolysis Studies

24
25
26
27 Pyrolytic analyses of luminescent argillites (B) and clayey-silty siliceous rocks above (A) and
28 below (C) these argillites are shown in Table 4. Pyrolysis was also performed on the same
29 samples after exhaustive extraction with chloroform in a Soxhlet apparatus (40hrs extraction).
30
31 It is important to note that all luminescent samples retained their luminescence after
32 extraction, confirming that the luminescence phenomenon is not related to the presence of the
33 free hydrocarbons extracted by chloroform.
34
35
36
37
38
39
40
41

42 The clayey-silty siliceous rocks under study have a high oil-generating potential
43 ($S_2 > 20$ mg/g; TOC > 4%). Their organic matter (OM) possesses a very high oil-generating
44 quality as characterized by its high hydrogen index (for example, HI > 700 mg of HC/g TOC at
45 low maturity $T_{max} < 435^\circ\text{C}$). The high quality organic matter and strongly reducing
46 conditions of sediment formation are consistent with low values of oxygen index (OI, Table
47 4). An increase in the maturity parameter T_{max} brings about decreasing HI (Fig. 13b). The
48 productivity index ($PI = S_1 / (S_1 + S_2)$) of these rocks rarely exceeds 0.10 (Table 4), which
49 corresponds to the beginning of the “oil window”. After extraction the S_2 and HI parameters

60
61
62
63
64
65

1 slightly decrease for the samples (Fig. 13). Here, the higher the maturity of OM, the larger the
2 change in the parameters, thus indicating a higher content of free generated HC (bitumoids).
3

4
5 The argillite luminescent layers show a much lower content of total organic carbon (TOC)
6 compared to the adjacent bituminous clay-silty siliceous layers (Table 4, Fig. 13). The oil-
7 generating potential of the luminescent layers is rather poor ($S_2 > 2.5$ mg/g; $TOC > 0.5\%$).
8 Their hydrogen index (HI) changes over a wide range of values from 150 to 500
9 mg HC/g TOC and does not depend on the T_{max} parameter. Also, T_{max} values are really
10 low for some individual samples ($< 410^\circ\text{C}$), which is perhaps caused mainly by the presence
11 of free HC (bitumoids) in the layers with low oil-generating potential. This is also consistent
12 with the very high values of the productivity index PI and the correlation between PI and
13 T_{max} (Table 4). It is possible that these free HC are not genetically bound to the OM of these
14 samples and are naturally migratory.

25
26
27
28
29
30

31 In contrast to the luminescent layer samples before extraction, the T_{max} values of these
32 samples after extraction are not extremely low and their T_{max} values become closer to each
33 other (Fig. 13b). However, there is still no correlation between HI and T_{max} for the
34 luminescent argillites after extraction, as opposed to the adjacent clayey-silty siliceous rocks
35 of the Bazhenov suite. The results suggest that the organic matter in the luminescent argillites
36 was not only depleted (diluted) by an abundant quantity of mineral (ash) material delivered to
37 the basin, but that its quality (HI) was also affected by different mechanisms of OM
38 transformation during sedimentation and diagenesis. Variations of oxygen index (OI) are
39 consistent with the effect of these changing factors as well as the levels of depletion (dilution)
40 from one episode to another during accumulation of the luminescent layers.

Optical microscopy leaves little doubt that the luminescent layers in the argillites of the BSF are in large part made up of volcanic material, as indicated by the intensely deformed and elongated shapes of their constituent particles and the specific micro-textures formed by these constituents. It is considered that many of the particles seen under the optical microscope represent devitrified volcanic glass and that the rock making up the luminescent layers can be described as a meta-tuffite. Van (1973) has shown that ash falls were widespread events throughout the Jurassic of the West Siberia basin. However, at the same time that these ash falls were taking place, the depositional sites of the luminescent layers were also receiving detrital inputs of silty material such as are characteristic of the BSF as a whole. It is envisaged that the ash falls acted as a single top-cutting influx of extraneous sediments into the predominantly silty material of the BSF.

Quantitative XRD shows that the luminescent layers are clay-rich (Table 1) and contain two types of clay minerals, namely a kaolin-rich mineral and a mineral which was identified as an ordered mixed-layer illite/smectite (Fig. 10 and 11). The kaolin mineral has a diffraction pattern consistent with well-ordered structure, but possibly with some dickite stacking. IR spectroscopy yields spectra in the OH-stretching range which are shown presence a dickite not only kaolinite (Fig. 12) and SEM images show that the kaolin mineral has a blocky structure built up of large aggregated stacks of crystals (Fig. 6a), which is also typical of for

dickite. It was concluded that the kaolin minerals in the luminescent layers consists of normal well-crystallized kaolinite with some dickitic layers.

XRD shows that some luminescent argillites contain a phase yielding a peak at 11.3Å which glycolation causes to expand to 12.1Å and heating at 550°C brings about contraction to about 10.1Å (Fig. 11). SEM images of thin sections of a luminescent sample rich in this material show a surface texture consisting of felted mass of tangled, interwoven pseudo-fibres as described above. EDS analysis shows this material to be highly aluminous with significant K and Mg, although some other areas are richer in Mg and Fe and contain correspondingly less Al. The presence of K in the EDS spectra of this material suggests that it is the dominant interlayer cation in the ordered mixed-layer I/S identified by XRD. That the K ion is indeed associated with pseudo-fibrous material can be seen in the element maps of Fig. 14 showing the distribution of elements that make up the major clay minerals in the luminescent layers.

TEM studies tend to confirm these observations but add other important details. In particular, it can be observed that the dispersed clay fraction of a luminescent layer rich in mixed-layer I/S consists of platy particles of irregular outline but with a substructure of lath-like particles in various orientations. Therefore, the dispersion appears to have been incomplete and the particles are still in an aggregated form (Fig. 7 and 8a). Thin laths at the edge of the aggregated particles yield a hexagonal single spot ED pattern and are therefore truly crystalline with 3-dimensional periodicity (Fig. 8a and 8b). Curled lath edges and aggregated particles yield ED patterns which may be described as turbostratic (continuous rings) as shown in Fig. 9a, although a degree of coherent stacking may be shown by rows of discrete but streaked hkl reflections as in Fig. 9b. These rolled up laths yield (00l) reflections of 10.2-10.3Å and contain K (as well as Si and Al) and are therefore typically micaceous in structure.

1 Non-clay minerals identified by EDS in the luminescent layers include pyrite, which yields a
2 spectrum consisting only of Fe and S peaks, and reaches a total of up to 5%. Calcite was also
3 identified by intense Ca and C peaks but must be a relatively minor phase as it was listed as
4 present by XRD in only two samples under study. In conjunction with morphology as shown
5 by SEM, quartz and feldspars were also distinguished by EDS analysis (Table 1).
6
7
8
9
10

11
12 Table 4 shows that the TOC in the luminescent argillites is much lower than that of the
13 clayey-silty siliceous sediments above and below them. The nitrogenous nature of the organic
14 matter in the luminescent argillites is noteworthy and calls for some explanation. In its initial
15 OM bioproduct state, nitrogen is present in proteins and amino acids which normally decay
16 during sedimentation. Depending upon the duration of the OM in its suspended state in the
17 oxygen saturated water, the proteins are either fully or partly lost. A characteristic feature of
18 sediment formation in the BSF is the strong reducing conditions where much of the nitrogen
19 is preserved in proteins. This leads to high nitrogen content in kerogen (Bogorodskaya et al.,
20 2005), as well as in the oils based on them (Goncharov, 1987). During diagenesis some
21 nitrogen is likely present in the nitrogen-containing organic structures of kerogen, which can
22 be closely associated with the clay surface by adsorption. It is worth mentioning that
23 luminescence phenomena observed in the clay phase of coals (Hessler, 1989) and kaolinite
24 pastes (Coyne et al., 1981; 1984) indicate a close bonding of nitrogen aromatics to mineral
25 surfaces. Langford and Blanc-Valleron (1990) analysed the amount of pyrolysable organic
26 material by plotting S₂ vs TOC for numerous shale samples. They found that in most cases
27 the organic matter is not completely pyrolysed and that the regression line does not pass
28 through the origin but intercepts the x axis. This is consistent with some resistant organic
29 matter being adsorbed by clay. Similarly, when S₂ was plotted against TOC for the
30 luminescent layers it was again found that the regression line did not quite pass through the
31 origin but intercepted the x axis indicating that about 0.5% organic matter was present,

1 presumably adsorbed on clay (Fig. 15). Although this may not be statistically significant it
2 should be recalled that gas analysis of the luminescent layers (Table 5) indicated the presence
3 of nitrogenous organic matter.
4
5

6
7
8 Nitrogen compounds from kerogen have mostly pyrrolic and pyridinic structures (Bennett
9 and Love, 2000) and fall in the range of organics studied by Coyne and co-authors (1981;
10 1984), which are found to promote the luminescence of kaolinite clay. The distribution of
11 organic compounds in source rocks and related crude oils have shown large and systematic
12 variation due to fractionation effects associated with the primary and secondary migration
13 processes (Yamamoto, 1992; Li et al., 1995). Bennett and Love (2000) studied samples of the
14 Kimmeridge Clay Formation and identified a significant range of nitrogen-containing organic
15 compounds and concluded that this indicates the formation of nitrogen compounds at a
16 relatively early stage of diagenesis. This possibly suggests that similar nitrogen compounds
17 may occur in the luminescent layers of the BSF which is close to the stratigraphic equivalent
18 of the Kimmeridge Clay.

36 5.2. Origin of the luminescent layers

37
38
39

40 The evidence outlined above indicates that some specific luminescent layers in inter-bedded
41 argillites of the BSF can be described as meta-tuffites and are analogous to K-bentonite
42 (kaolinitic K-bentonite) and are composed primarily of volcanic ash material, but with a
43 significant contribution of silt-sized minerals of terrigenous origin that are typical of the BSF
44 as a whole. The clay mineralogy of these luminescent layers is undoubtedly almost
45 exclusively authigenic in origin as shown by the extraordinary morphology of the
46 kaolinite/dickite and ordered mixed-layer I/S clays which is clearly incompatible with normal
47 detrital sedimentation. As for the conditions under which the kaolin minerals formed,
48 although Ehrenberg et al. (1993) suggested that kaolinite transformed to dickite at about 3 km
49

1 depth at temperatures of 120-130°C in Mesozoic sandstones of the North Sea, later studies by
2 Beaufort et al. (1998) and Lanson et al. (2002) suggest that a progressive transformation to
3 dickite can occur at lower temperatures and more shallow depths as a result of kinetic and
4 other factors.
5
6
7
8
9

10 With regard to the origin of the ordered mixed-layer I/S mineral, the conventional wisdom at
11 the present time is that this develops from a smectitic precursor from randomly ordered
12 mixed-layer illite-smectite at temperatures in the 80-90°C range, either by a layer-by-layer
13 transformation of smectite to illite or by a dissolution/precipitation mechanism (Środoń et al.,
14 2009; Wilson, 2013 and references therein). The fact that the luminescent layers are to a large
15 extent derived from altered volcanic ash, and are therefore likely to have provided smectitic
16 clays through the alteration of volcanic glass, may be viewed as supporting this general
17 concept.
18
19
20
21
22
23
24
25
26
27
28
29
30

31 The possibility that the kaolinite and ordered I/S minerals may be a direct cause of
32 luminescence should be considered, particularly bearing in mind the findings of Götze et al.
33 (2002) that in general all dioctahedral clay minerals show visible cathodoluminescence (CL)
34 whereas the trioctahedral clay minerals do not. Both kaolinite and dickite minerals show a
35 characteristic deep blue CL and, as noted above, the ordered I/S clay mineral also has a
36 dioctahedral structure. Walker and Burley (1991) recorded bright, sky blue CL emission as
37 typical of pore-filling and grain replacing kaolinite and noted that kaolinite showed a broad
38 emission band at ~400nm and a distinct shoulder at ~350nm in the UV at room temperature.
39 They further noted that at least half of the CL intensity of this broad band was emitted in the
40 UV. Götze et al. (2002) observed that the characteristic blue CL of kaolinite and other
41 dioctahedral minerals was caused by an intense emission band at ~400nm, comprising a
42 double peak at 375 and 410 nm respectively, and related this to radiation-induced defect

1 centres, probably related to silicon-oxygen (Si – O) or aluminium-oxygen (Al – O – Al) bonds
2 (Götze, 2012). Such defects are usually induced by bombardment of alpha particles
3
4 (Marshall, 1988). Table 2 shows that the luminescent layers contain radioactive elements, as
5
6 determined by two methods of analysis, at concentrations far above those normally
7
8 encountered in shales. Thus, the luminescent layers dominated by well crystalline kaolin
9
10 minerals contain uranium ranging from 11 to 67 ppm and thorium from ~1 to 76 ppm. Where
11
12 the luminescent layers contain both kaolinite and ordered mixed-layer I/S clays uranium
13
14 ranges from 20 to 80 ppm and thorium from 32 to 77 ppm.
15
16
17
18
19
20

21 Bearing in mind that the luminescent argillites are more clay-rich than the clayey-silty
22
23 siliceous sediments of the BSF as a whole, and that the clay minerals that they contain have
24
25 an extraordinary authigenic morphology and were derived from altered volcanic ash, then it
26
27 would seem logical to relate these special factors to their luminescent characteristics in the
28
29 UV. It should be noted, however, that while well crystalline kaolin minerals occurred in the
30
31 luminescent layers in all of the 10 cores studied, the ordered mixed-layer I/S mineral
32
33 occurred only in 6 of them. Therefore, the presence of well crystalline kaolinite (with at least
34
35 some dickite additives) is a common factor in the luminescent layers and on this basis is
36
37 thought to be the major contributor to the luminescence of the argillites in the BSF.
38
39
40
41
42
43

44 However, a possible role for organic matter, whether in discrete form or adsorbed on clay, in
45
46 giving rise to the luminescence is also worth examining in more detail, even though the
47
48 argillites have a much lower TOC than the non-luminescing sediments immediately above
49
50 and below them (Table 4). Nevertheless, the small amount of organic matter present in the
51
52 luminescent layers is unexpectedly quite nitrogenous in some samples (Table 5), suggesting a
53
54 possible genetic link with luminescence. It is envisaged that in the initial bio-product state of
55
56 organic matter, nitrogen was present as proteins and amino acids which would normally
57
58
59
60
61
62
63
64
65

1 quickly decay when present in the oxygenated upper water column. However, because the
2 luminescent layers are derived from volcanic ash, it is possible that the ashy sediment could
3 transit more quickly through the oxygenated layers of the water column entraining within it
4 some of the suspended relatively fresh organic matter. Once deposited on the deep-sea floor,
5 this organic matter was preserved by the strongly reducing, anoxic conditions that are
6 characteristic of the BSF, and possibly by adsorption on to clay minerals.
7
8
9
10
11
12
13
14

15 To clarify the question of whether the luminescence in the argillites was due to organic
16 matter or to the nature of their clay minerals, a luminescent sample was heated at 400, 500,
17 700, 800 and 900°C. After heating to each temperature, the luminescence of the sample was
18 photographed under day light and UV (Fig. 16) and then analysed on an FTIR-spectrometer
19 (Fig. 17). The sample photographed under UV showed that the intensity of luminescence
20 significantly decreased around 400°C and practically disappeared at 500°C. Although this
21 result might be reasonably attributed to the thermal decomposition of organic matter,
22 beginning at ~300°C and completed at 500°C, it is also consistent with the observation that
23 the luminescence in most materials decreases with increasing temperature (Marshall, 1988).
24
25 Also, it is noteworthy that although the clayey-silty siliceous rocks of the BSF contain
26 abundant nitrogenous organic matter, they do not luminesce under UV in the same way as the
27 luminescent layers in the argillites. It is concluded, therefore, that the luminescence of the
28 argillite layers is more likely to be related to clay mineralogy rather than to organic matter.
29
30 However, the latter cannot be completely discounted as accounting for at least some of the
31 luminescence.

52 5.3. Significance of the luminescent layers

53
54 If the luminescent layers are accepted as having formed from volcanic ash falls of wide
55 lateral extent, and that it is reasonable to describe them as meta-tuffites, then there is a wide
56
57
58
59
60
61
62
63
64
65

1 possible range of alternative names. For example, the illite-smectite type illustrated by upper
2 layers in Figure 3 could be regarded a K-bentonites, while the kaolin type in the lower layers
3 shown in Figure 3 could be regarded as kaolinitic bentonites. Because they have a unique
4 position within the Bazhenov Shale Formation in general then it is evident that they could be
5 as useful in oilfield exploration as tonsteins and K-bentonites are in coalfield and other
6 geological explorations (Środoń, 1972; Somelar et al., 2009; Warren, 2016; Dai et al., 2017).
7 In fact, the characteristics of the luminescent layers can be usefully compared with those of
8 tonsteins in that they both derive from laterally extensive ash falls that have been altered to
9 highly crystalline kaolin minerals in a strongly reducing environment. A plot of the Zr/TiO_2
10 and Nb/Y ratios of luminescent layer samples on the magmatic discriminant diagram of
11 Winchester and Floyd (1977) places them in the Rhyo-dacite/Dacite field (Fig. 18). Such a
12 magmatic source is relatively high in Al and it seems probable that this could explain the high
13 alumina clay minerals in the luminescent layers. However, the differences between the
14 luminescent layers and tonsteins are equally significant. Tonsteins have formed at or very
15 near land surface whereas the luminescent layers of the argillites, in common with much of
16 the BSF, are deep water deposits.

25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40 Spears (2012) pointed out that the evident stratigraphic value of tonsteins has been much
41 enhanced by recent geochemical studies, particularly those involving radiometric age dating
42 and detailed trace element analysis. These studies suggest that a chemostratigraphic approach
43 can be used to characterize and identify particular tonsteins, thus providing useful
44 benchmarks in coalfield exploration. Evidently, the luminescent layers in the BSF may also
45 have the potential to be used for exploration of hydrocarbons in a similar way. We are only at
46 the beginning of such activity compared with tonstein studies which have been proceeding
47 for well over a century.

1 It should be emphasized that the clay mineralogy of the luminescent layers may well be
2 sensitive to environmental changes, involving possible dickitization of kaolinite with
3
4 concomitant formation of ordered mixed-layer I/S, with both processes being able to relate to
5
6 the position of the adjacent sediments to the oil window. It is concluded, therefore, that wider
7
8 and more systematic study of the mineralogy and geochemistry of the luminescent layers of
9
10 argillites in the West Siberian Basin may be a worthwhile exercise in the search for new
11
12 hydrocarbon resources.
13
14
15
16

17 **6. Conclusions**

18 Luminescent layers of unusual intensity under UV radiation occur in argillites in the
19
20 Bazhenov Shale Formation (BSF) of the West Siberia Basin and extend over a wide lateral
21
22 area of more than hundreds of square kilometers. Optical microscopy shows convincingly
23
24 that these layers represent altered volcanic ash falls and may be described as meta-tuffites or
25
26 K-bentonites. The luminescent layers are clay rich but deficient in organic matter compared
27
28 with the sediments above and below them. The main clay minerals in the luminescent layers
29
30 are a kaolin mineral consisting of kaolinite with a certain amount of dickite additives, as well
31
32 as an ordered mixed-layer illite-smectite (I/S) which occurs in aggregates of distinctive felted
33
34 masses. Both clays are of authigenic origin and were derived from altered volcanic ash
35
36 material. The origin of the unusually intense luminescence under UV of the argillites in the
37
38 Bazhenov Shale is broadly related to their dioctahedral clay mineralogy, but especially to its
39
40 content of well crystalline kaolin minerals due to radiation induced defects brought about by
41
42 their high uranium and thorium contents. In some ways the luminescent layers may be
43
44 compared with tonsteins and K-bentonite spread located in different geological environment
45
46 especially with regard to their general stratigraphic significance, and the fact that they contain

2
3 1984), which are found to promote the luminescence of kaolinite clay. The distribution of
4 organic compounds in source rocks and related crude oils have shown large and systematic
5 variation due to fractionation effects associated with the primary and secondary migration
6 processes (Yamamoto, 1992; Li et al., 1995). Bennett and Love (2000) studied samples of the
7 Kimmeridge Clay Formation and identified a significant range of nitrogen-containing organic
8 compounds and concluded that this indicates the formation of nitrogen compounds at a
9 relatively early stage of diagenesis. This possibly suggests that similar nitrogen compounds
10 may occur in the luminescent layers of the BSF which is close to the stratigraphic equivalent
11 of the Kimmeridge Clay.

22 5.2. Origin of the luminescent layers

23
24

25 The evidence outlined above indicates that some specific luminescent layers in inter-bedded
26 argillites of the BSF can be described as meta-tuffites [as meta-tuffites and are analogous to](#)
27 [K-bentonite \(kaolinitic K-bentonite\)](#) and are composed primarily of volcanic ash material, but
28 with a significant contribution of silt-sized minerals of terrigenous origin that are typical of
29 the BSF as a whole. The clay mineralogy of these luminescent layers is undoubtedly almost
30 exclusively authigenic in origin as shown by the extraordinary morphology of the
31 kaolinite/dickite and ordered mixed-layer I/S clays which is clearly incompatible with normal
32 detrital sedimentation. As for the conditions under which the kaolin minerals formed,
33 although Ehrenberg et al. (1993) suggested that kaolinite transformed to dickite at about 3km
34 depth at temperatures of 120-130°C in Mesozoic sandstones of the North Sea, later studies by
35 Beaufort et al. (1998) and Lanson et al. (2002) suggest that a progressive transformation to
36 dickite can occur at lower temperatures and more shallow depths as a result of kinetic and
37 other factors.

Fig. 6. (a) SEM image of polished, carbon-coated thin sections of luminescent layers (in back-scattered electron mode) showing large blocky crystalline aggregates to left of field and a felted pseudo-fibrous texture to the right of the field, (b) EDS spectrum of blocky aggregates showing kaolinitic composition and (c) EDS spectrum of felted pseudo-fibrous material showing its aluminous composition but with significant K and Mg.

Fig. 7. Bright field TEM image of the clay fraction of luminescent argillite from core P-1 showing thick aggregates of irregularly shaped platy particles, some with curled edges resembling fibres.

Fig. 8. (a) Bright field TEM image of thick plate-like particle clearly showing a sub-structure of lath-like particles and (b) Selected area electron diffraction pattern from the edge of particle region shown in Fig. 8(a).

Fig. 9. (a) Selected area electron diffraction pattern from aggregated particle showing turbostratic ordering and (b) Selected area electron diffraction pattern from rolled up edge of platy particle showing (00l) and (hk0) reflections.

Figure 10. XRD patterns (CuK α radiation) of bulk samples of randomly oriented kaolinite-rich luminescent argillite. Values of d-spacing are given in angstroms. Mineral identification: I/S - illite-smectite mixed layered minerals, K - kaolinite, Q – quartz, F – feldspars, P - pyrite, M - marcasite, C - calcite

Figure 11. XRD patterns of the bulk sample (a) and clay fraction (b) of oriented illite-rich argillite (sample P-1) in air-dried (blue), glycol solvated (red) and heated at 550°C (yellow). Values of d-spacing are given in angstroms. Mineral identification: I/S - illite-smectite mixed layered minerals, K - kaolinite, Q – quartz, F – feldspars, P - pyrite, M - marcasite, C – calcite

Fig. 12. IR spectra of (a) a luminescent argillite sample from D-9 well; (b) well-crystallized kaolinite from Georgia, USA and (c) dickite from Anglesey, North Wales.

Fig. 13. Characterisation of (a) oil-generating potential and (b) maturity and type of organic matter (OM) of A, B and C layers of the Bazhenov Shale Formation. (A and C - clayey-silty siliceous shales; B - luminescent argillites).

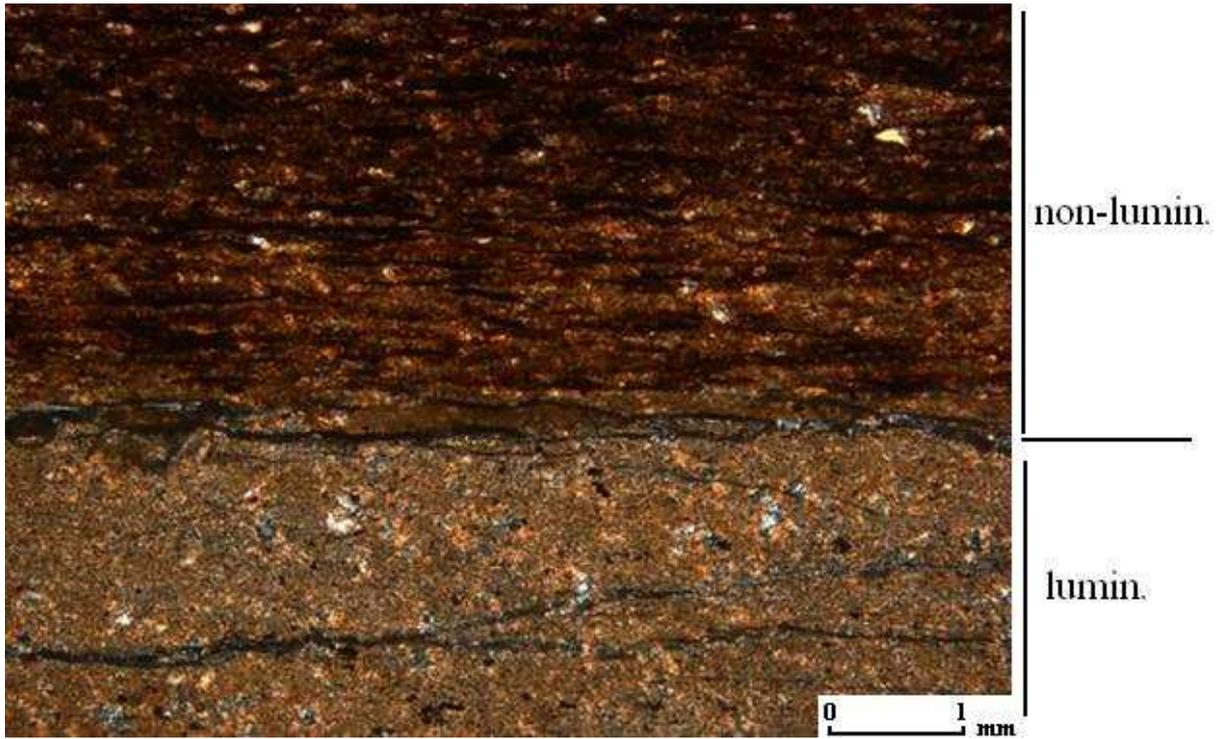

Fig. 1. Polished cross section of non-luminescing, organic-rich clayey-silty siliceous shale (dark upper layer) and organic-poor argillite (light lower layer) from the BSF.

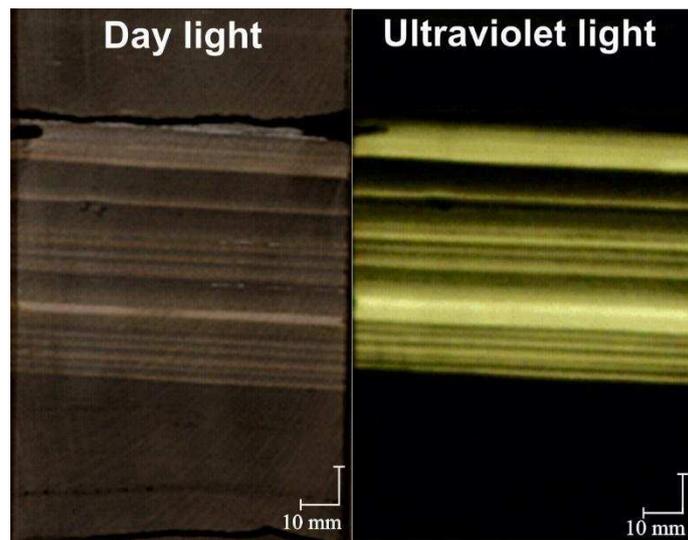

Fig. 2. Appearance of luminescent layers in argillite of the BSF in daylight and under UV radiation.

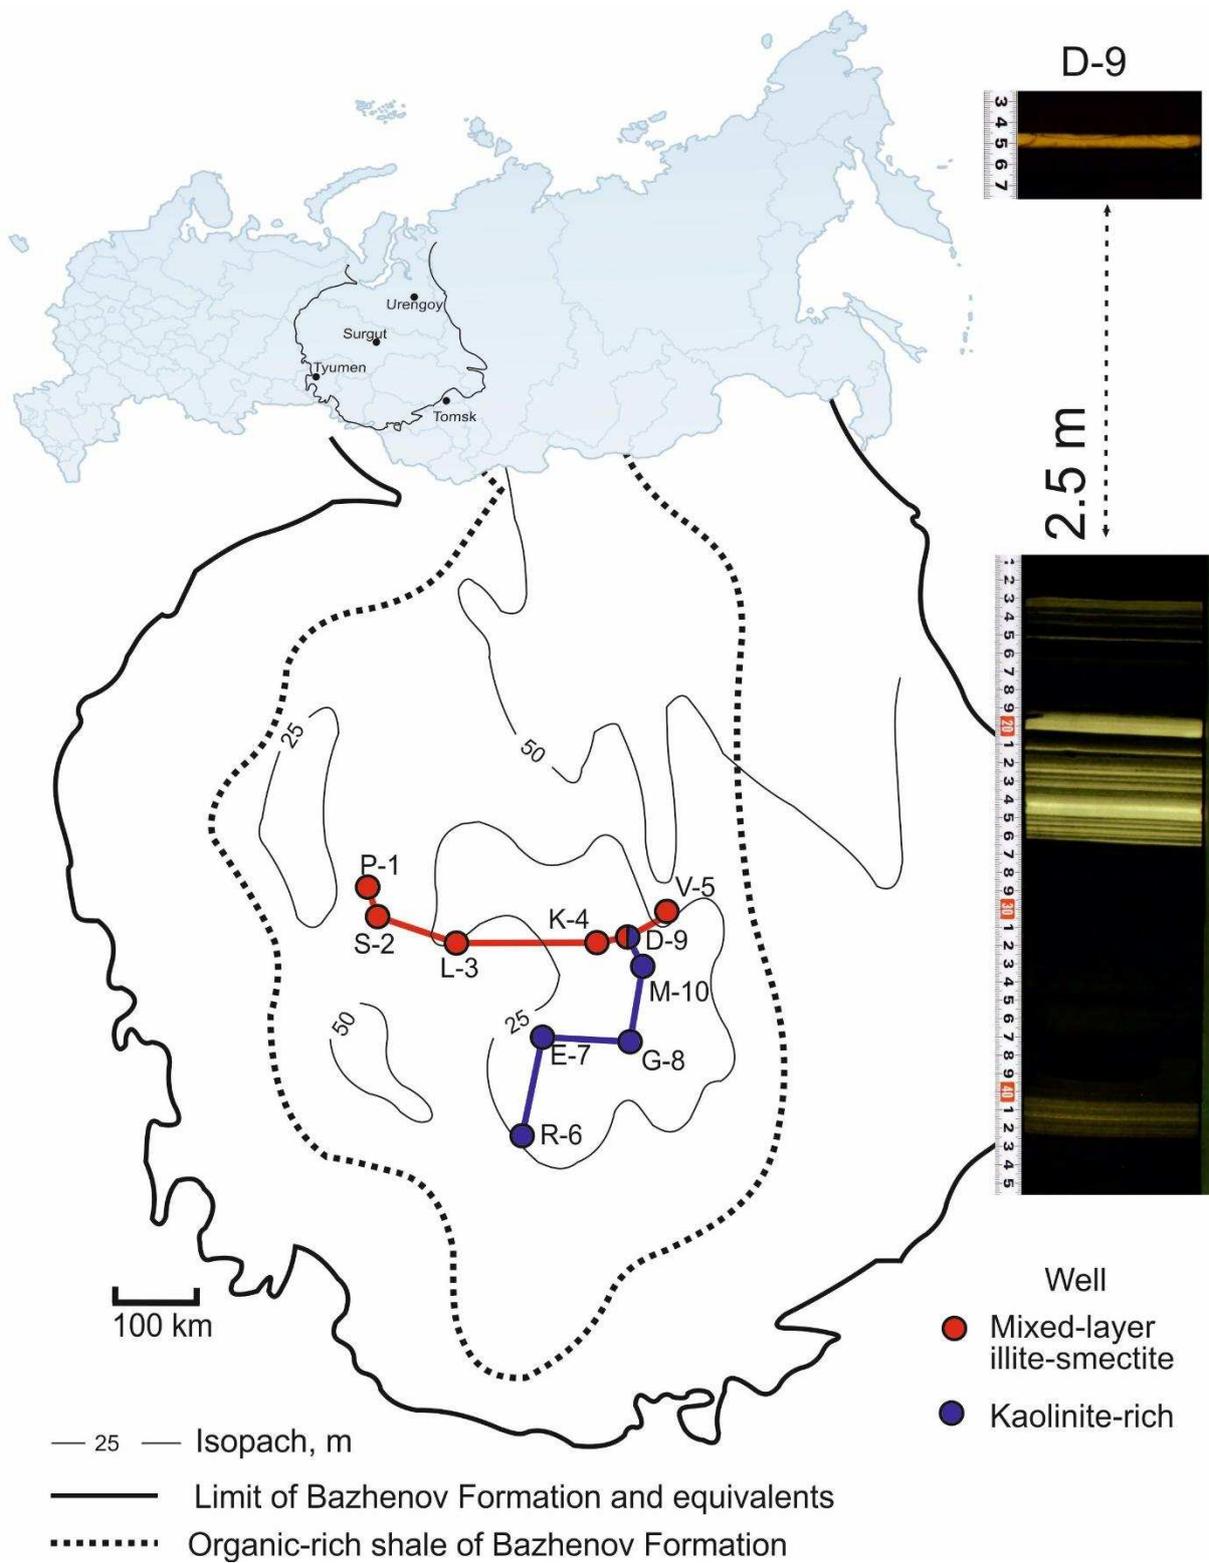

Fig. 3. Well locations in the Bazhenov shale deposit (inset showing wider location in West Siberia and scale).

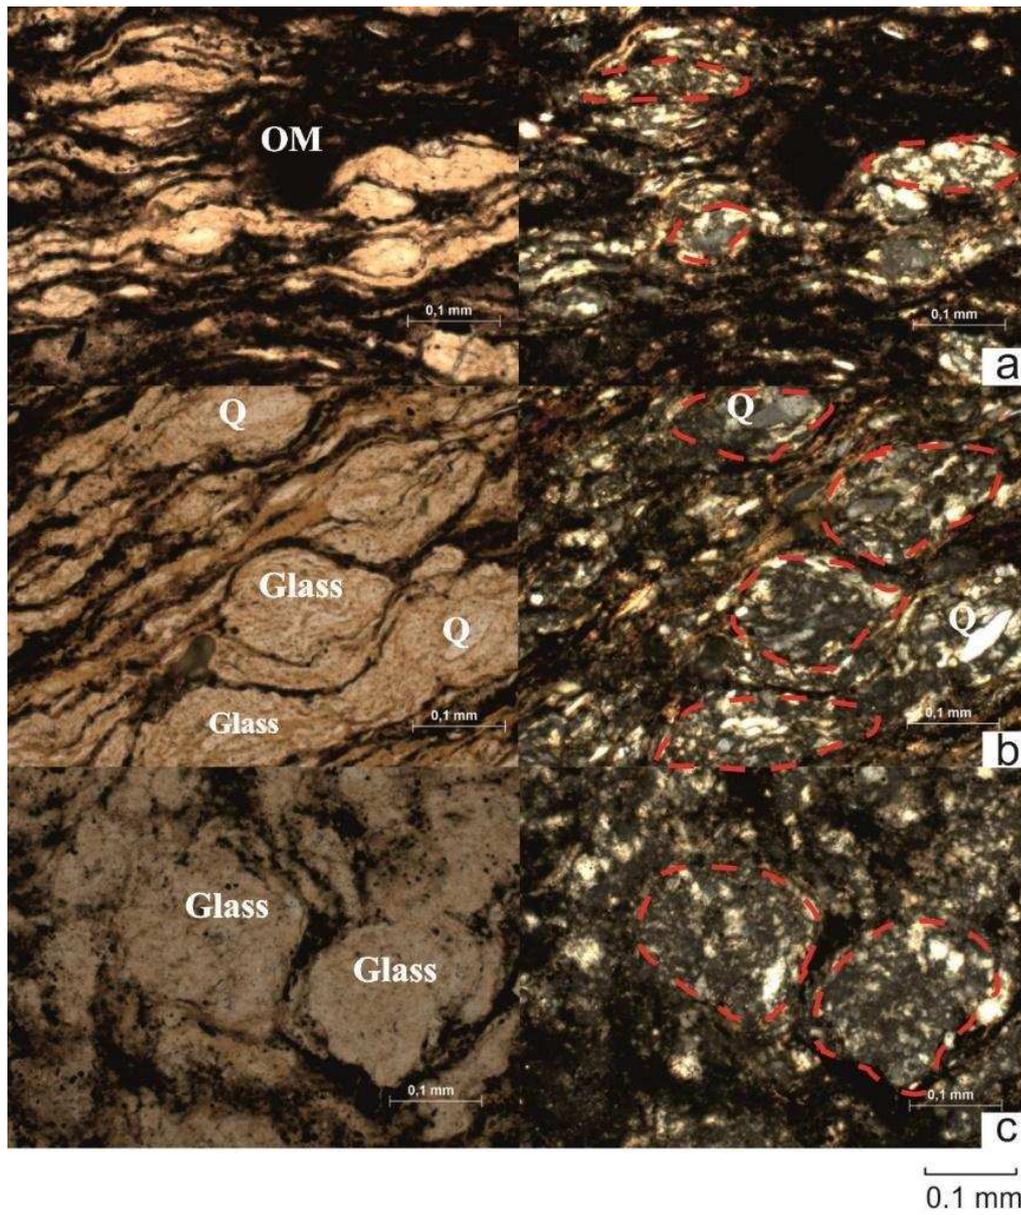

Fig. 4. Optical micrographs showing the fabric of the luminescent layers of various thicknesses in the BSF in well D-9: A and C in orthogonal lamination, B – parallel lamination. Plane polarized light (left) and crossed polars (right). Notes: red circles - “volcanic debris” (or Glass); Q - quartz; OM – organic matter.

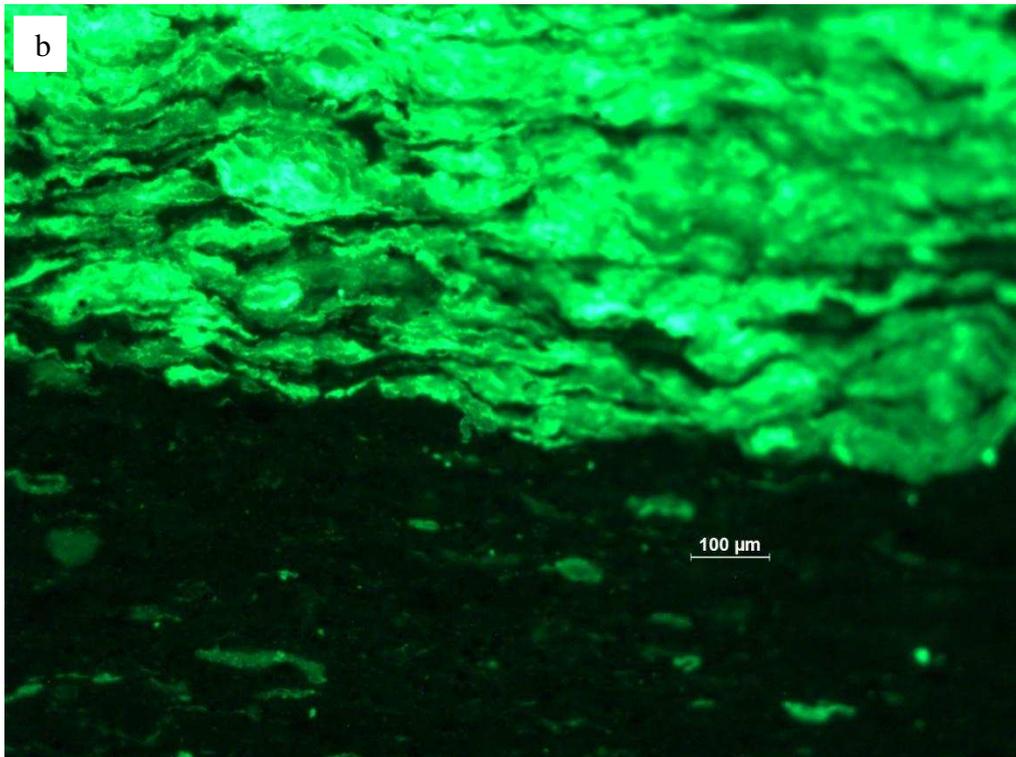

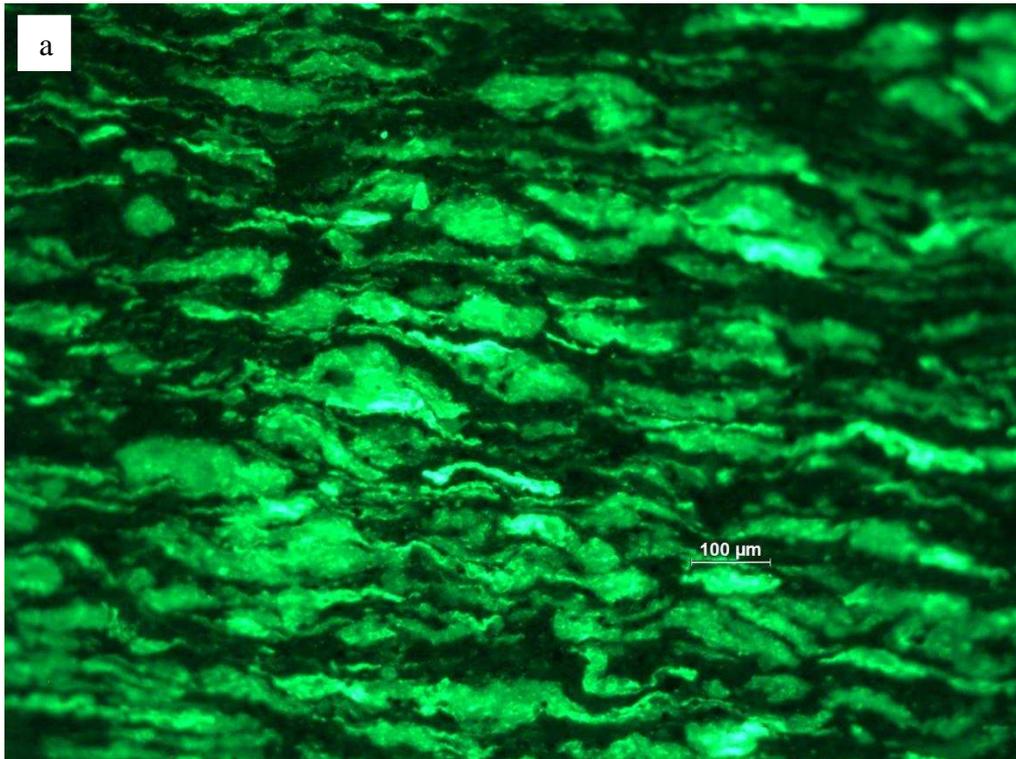

Fig. 5. Fluorescence micrographs of argillite showing (a) discrete luminescent irregularly shaped volcanic ash particles and (b) junction between argillite and non-luminescent clayey-silty siliceous layer of BSF.

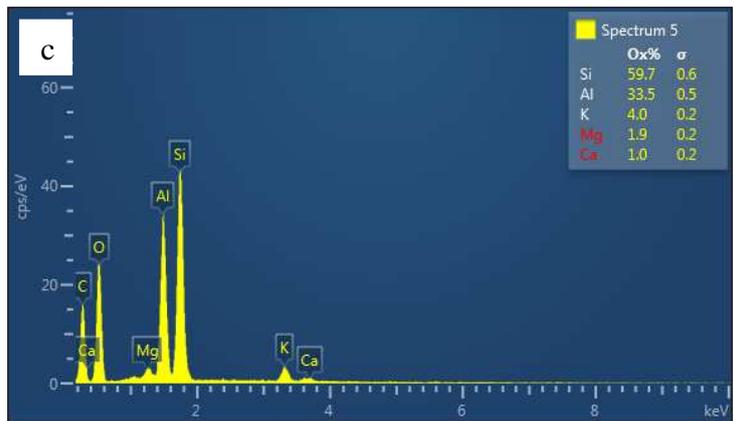

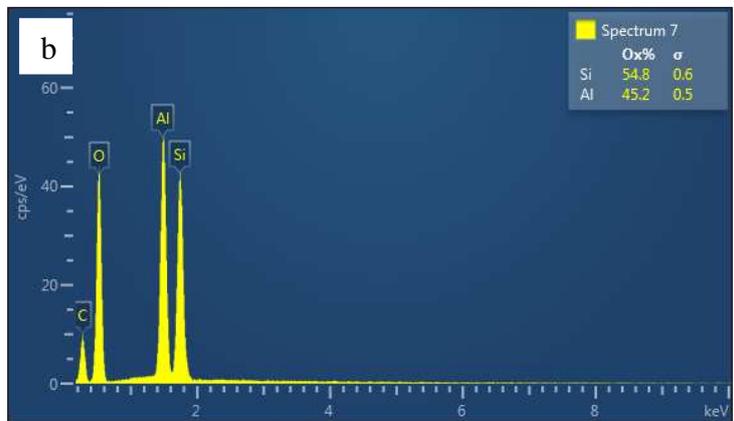

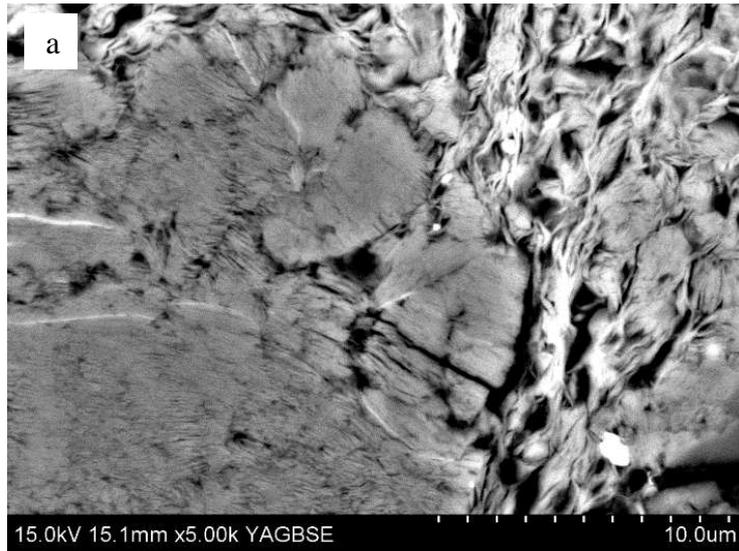

Fig. 6. (a) SEM image of polished, carbon-coated thin sections of luminescent layers (in back-scattered electron mode) showing large blocky crystalline aggregates to left of field and a felted pseudo-fibrous texture to the right of the field, (b) EDS spectrum of blocky aggregates showing kaolinitic composition and (c) EDS spectrum of felted pseudo-fibrous material showing its aluminous composition but with significant K and Mg.

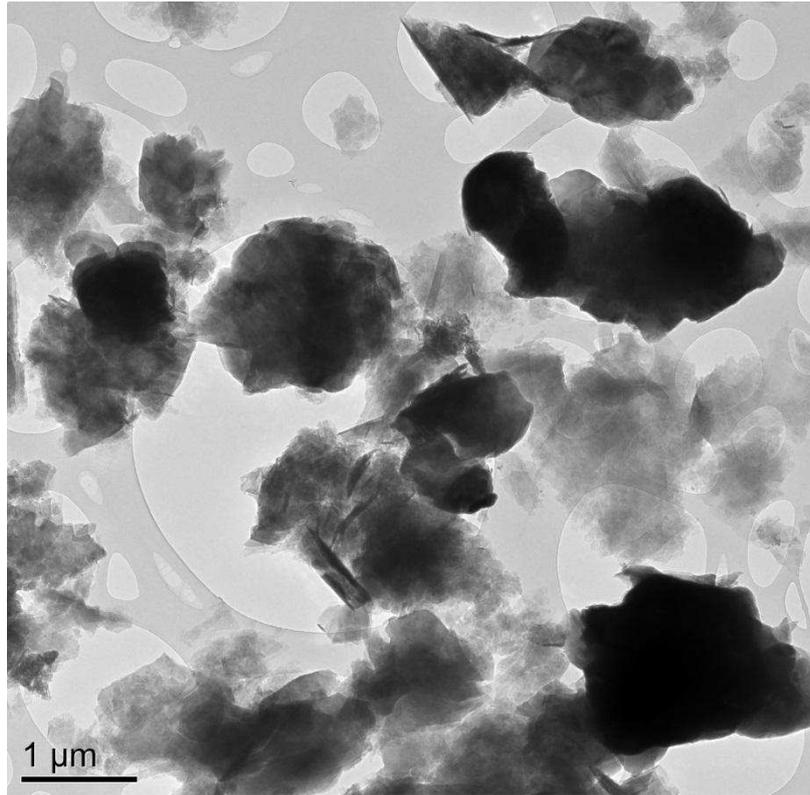

Fig. 7. Bright field TEM image of the clay fraction of luminescent argillite from core P-1 showing thick aggregates of irregularly shaped platy particles, some with curled edges resembling fibres.

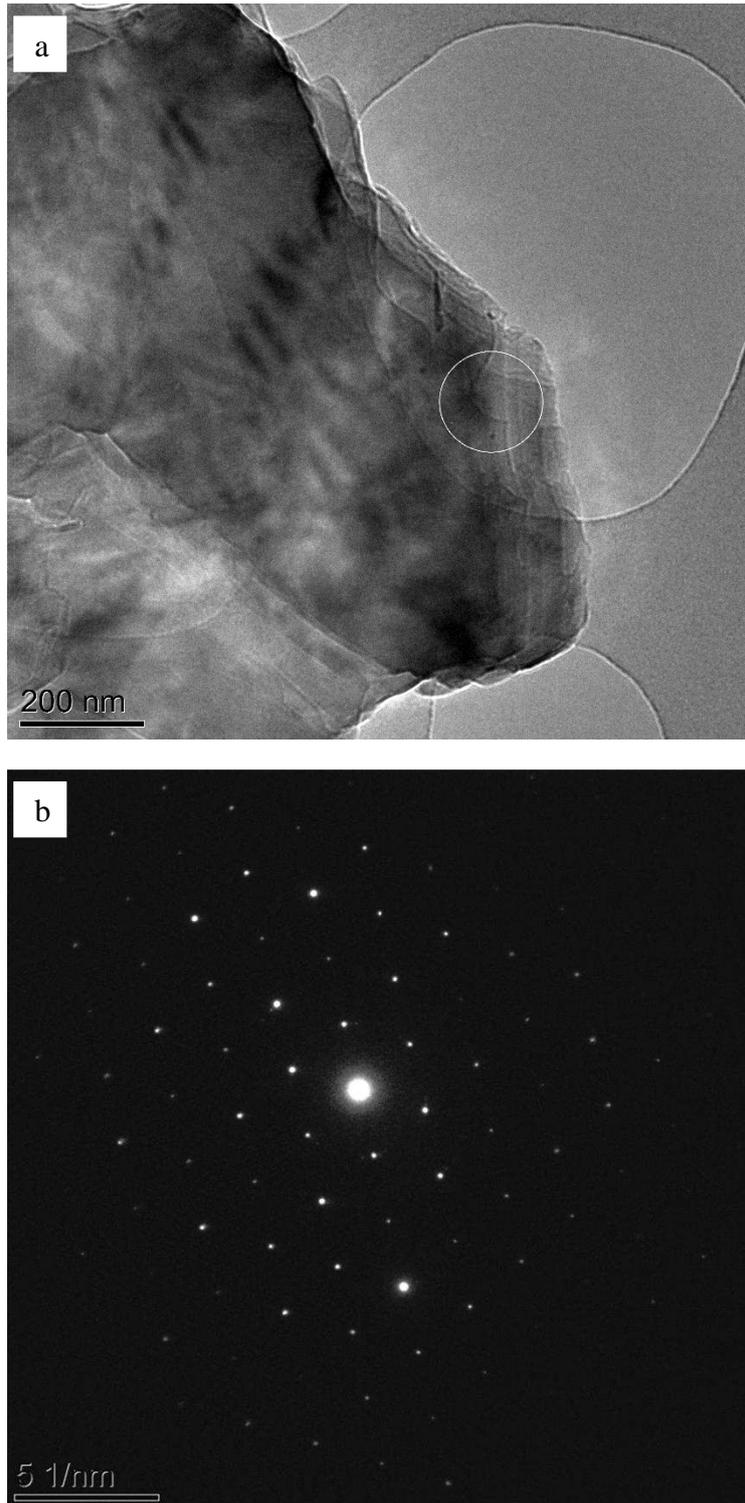

Fig. 8. (a) Bright field TEM image of thick plate-like particle clearly showing a sub-structure of lath-like particles and (b) Selected area electron diffraction pattern from the edge of particle region shown in Fig. 8(a).

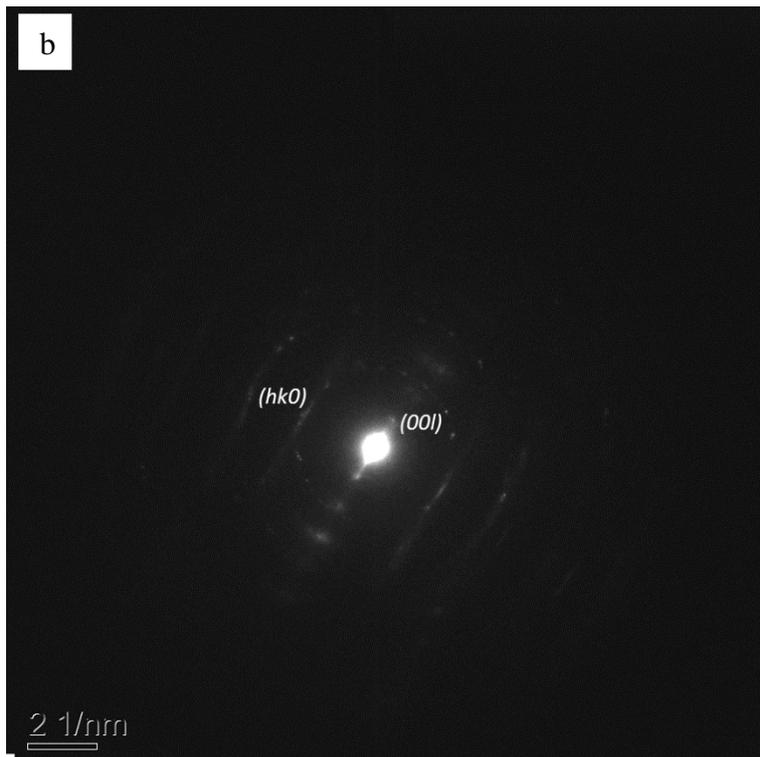

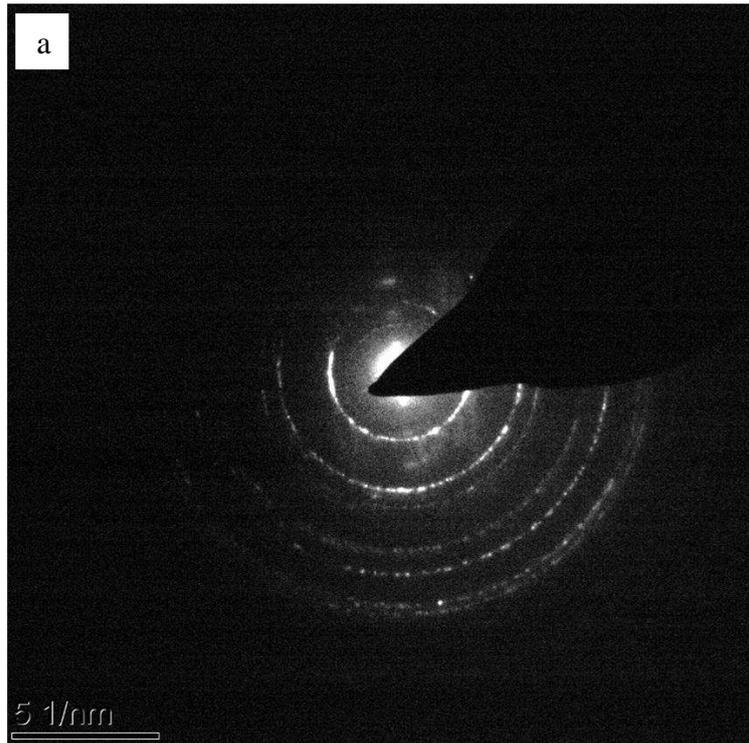

Fig. 9. (a) Selected area electron diffraction pattern from aggregated particle showing turbostratic ordering and (b) Selected area electron diffraction pattern from rolled up edge of platy particle showing (00l) and (hk0) reflections.
