Orientalional order in the splay nematic ground state†

Richard J. Mandle ^a and Alenka Mertelj ^b

Modulated nematic liquid crystal phases, which lack positional order but have some periodic variation in the direction of average orientation present in a classical nematic, have attracted significant interest. In the recently discovered splay nematic (N_S) phase the average orientational order is augmented with a periodic splay deformation of orientation perpendicular to the director. We use X-ray scattering experiments to measure the orientational order parameters in the nematic (N) and splay nematic (N_S) phases of the liquid crystalline material RM734. The degree of orientational order is somewhat larger in the N_S phase than in the preceding nematic and temperature dependent. We reconstruct the orientational distribution function and find it to be nematic-like in the N_S phase, indicating the change in orientation between neighbouring molecules due to the splay modulation is very small. A small splay angle implies that the splay modulation period is larger than the few tens of nanometers originally envisaged. The method described herein can be used to assist in unambiguous identification of the splay-nematic phase.

Introduction

Nematic liquid crystal phases, in which there is an average orientational order of the molecules but a lack of positional order, are the cornerstone of the display industry. New nematic ground states are rare, and in the 21st century the prediction and subsequent discovery of nematic phases with periodic modulation of their orientation has generated significant interest.^{1–5} The most widely studied of these recently observed nematic variants is the twist-bend nematic (N_{TB}), in which the average orientational direction precesses about a cone along the optic axis giving rise to a helical structure with a periodicity of a few molecular lengths.^{6–8}

Some years ago we reported rod-shaped materials which exhibit two nematic phases separated by a weak first order phase transition.⁹ One of these materials (RM734, Fig. 1A)¹⁰ was studied in detail by Mertelj *et al.*, who found the higher temperature phase to be a classical nematic phase, and the lower temperature nematic to be a nematic phase with a periodically splayed local director – a splay nematic phase (N_S , Fig. 1C).¹¹ The experimental observation of the splay nematic ground state satisfied an earlier prediction of such a phase.¹² Chaturvedi and Kamien recently discussed how the N_S is related to the splay-bend nematic phase (N_{SB}) described by

Dozov through exchange of the splay and bend elastic constants;^{1,13} the modulation vector is perpendicular to the director in the N_S phase and parallel in the N_{SB} . It is possible that the ‘MP’ phase reported by Kikuchi *et al.* is another example of the splay nematic phase.¹⁴ Barbero and Lelidis recently discussed the possibility

of periodic modulated splay-nematic phases that results from a negative value of K_{11} .¹⁵ The proposed structure of the N_s phase is polar, biaxial and antiferroelectric and therefore of significant interest for electrooptic devices. However, there is a need to better characterise the structure of this phase, and to devise methods for unambiguous identification.

For the twist-bend modulated nematic phase, X-ray scattering experiments can be used to measure the order parameters which can then be used to calculate the heliconical tilt angle.^{7,8} From the proposed model of the N_s phase¹¹ one can imagine that the periodicity of the splay-nematic phase is inversely related to the splay-angle between neighbouring molecules, *i.e.* a large periodic length scale leads to a small angle and *vice versa*. In the case of a small periodic length scale, this angle may be measurable by X-ray scattering experiments. However, its absence would support the idea that the periodic length scale of the N_s phase is large, rather than being on the order of a few nanometers.

Experimental

Materials used in this study were prepared as described previously.¹⁰ The first five even orientational order parameters ($\langle P_n \rangle$) of RM734 were determined by wide angle X-ray scattering (WAXS) using the method described in ref. 16 and 17. Samples were filled into 0.9 mm I.D. borosilicate glass capillary tubes purchased from Capillary Tube Supplies UK Ltd. Briefly, 2D WAXS patterns were recorded as a function of temperature in 3 °C intervals over a temperature range of 195 °C to 48 °C (T/T_{N-iso} range of 1.01 to 0.69) with an exposure time of 300 seconds and a sample to detector distance of 121 mm, allowing simultaneous recording of small and wide angle data. The 2D WAXS pattern obtained from an empty glass capillary was used as a background. Following background subtraction we performed azimuthal integration (1° step size). Fitting according to eqn (1) allows the orientational order parameters to be determined; eqn (2) and (3) show this for $\langle P_2 \rangle$ while details for higher order parameters are given in the ESI.†

$$I(X) = \sum_0^{\infty} \frac{\pi}{2} f_{2n} \frac{(2n-1)!!}{2^n n!} \cos^{2n} X \quad (1)$$

$$\langle \cos^2 \beta \rangle = \frac{\sum_{n=0}^{\infty} f_{2n}}{\sum_{n=0}^{\infty} 2n+3} \bigg/ \frac{\sum_{n=0}^{\infty} f_{2n}}{\sum_{n=0}^{\infty} 2n+1} \quad (2)$$

$$\langle P_2 \rangle = \frac{1}{2} (3 \langle \cos^2 \beta \rangle - 1) \quad (3)$$

Form factors and scattering intensities were calculated from atomic coordinates using the ATSAS 2.8 software package.^{18–20}

Results and discussion

As discussed in an earlier paper, when studied by X-ray scattering experiments the wide-angle peak RM734 (and related materials) is found over a particularly large angular range and

Fig. 2 (a) Plot of the calculated molecular form factor ($P(Q)$) of RM734. (b) Plot of the calculated wide angle scattered intensity of RM734. (c) Plot of experimentally measured scattered intensity versus Q (\AA^{-1}) for the wide-angle peak(s) of RM734 in the isotropic liquid at 190 °C. In all three plots the solid line corresponds to data – either calculated or experimental – and dashed lines to deconvoluted peaks.

can be deconvoluted into two overlapping peaks (Fig. 2c) at 1.14 \AA^{-1} and 1.49 \AA^{-1} . This behaviour is observed not only in the N_s phase, but also in the nematic and isotropic liquid. If both wide-angle peaks originate from a single molecule then the analysis presented in eqn (1)–(3) can still be used, whereas if one of the peaks originates from local phase biaxiality in the N_s phase then this approach may no longer be valid. That the two wide angle peaks are observed in the isotropic liquid and both nematic phases are strong indicators that they do not originate from biaxial local order, however we sought further demonstration that these originate from the molecular shape of RM734 by calculating the molecular form factor (Fig. 2a) and scattered intensity profile (Fig. 2b). The molecular form factor of RM734 shows two diffuse features whose scattering vectors (1.15 \AA^{-1} and 1.44 \AA^{-1}) match both calculated isotropic wide-angle scattering data (Fig. 2b) and experimental scattering data in the isotropic liquid (Fig. 2c). Plots of intensity versus Q for the nematic and N_s phases are given in the ESI,† (Fig. S12); these show that the position of the deconvoluted peaks does not vary in the different phases (Iso, N, N_s), which is to be expected given their origin in molecular shape.

Having established the origin of the two wide angle peaks, we next measured the orientational order parameters of RM734 as a function of temperature across the nematic and N_s phases. As shown in Fig. 3, both $\langle P_2 \rangle$ and $\langle P_4 \rangle$ increase across the nematic phase, reaching maximum values of ~ 0.55 and ~ 0.15 , respectively. At the N_s –N transition there is a jump in both $\langle P_2 \rangle$

Fig. 3 Plot of the first four even order parameters $\langle P_n \rangle$ as a function of reduced temperature for RM734. We omit $\langle P_{10} \rangle$ from this plot as it is effectively zero at all temperatures. The dashed line corresponds to the location of the N_S -N phase transition.

and $\langle P_4 \rangle$; in the splay nematic phase we find values in the range ~ 0.60 – 0.66 and ~ 0.20 – 0.27 for $\langle P_2 \rangle$ and $\langle P_4 \rangle$, respectively. Values of $\langle P_6 \rangle$ follow the same trend as $\langle P_2 \rangle$ and $\langle P_4 \rangle$, being in the range 0.00 – 0.04 in the nematic phase, and 0.05 – 0.10 in the N_S phase. We also determined the higher order parameters $\langle P_8 \rangle$ and $\langle P_{10} \rangle$; the former is zero in the nematic phase and increases slightly to take a maximum value of ~ 0.03 in the N_S phase, whereas the latter is effectively zero at all temperatures studied. We note that at the N_S -N phase transition there is a clear discontinuity in the first three order parameters, which is to be expected due to the first order nature of this phase transition.

Plotting $\langle P_4 \rangle$ versus $\langle P_2 \rangle$ allows us to remove the explicit temperature dependence of the two principal order parameters, as shown in Fig. 4. Empty data points correspond to RM734 in the nematic phase; filled data points correspond to the splay-nematic phase of the same material. This shows that the relationship between $\langle P_2 \rangle$ and $\langle P_4 \rangle$ is the same in the nematic and N_S phases of RM734, with values simply being larger in the

Fig. 4 The variation of $\langle P_4 \rangle$ as a function of $\langle P_2 \rangle$ for RM734: empty data points correspond to values in the nematic phase (>132.7 °C), filled data points correspond to values in the splay nematic phase (<132.7 °C). Predictions from Maier-Saupe theory (solid line) are given for comparison.

lower temperature nematic phase. Experimental orientational order parameters were compared with Maier-Saupe (MS) theory, presented as a solid black line. It is immediately apparent that, at a given value of $\langle P_2 \rangle$ the corresponding value of $\langle P_4 \rangle$ is smaller than is predicted by either MS theory. It should be noted that MS theory is concerned with predicting the orientational properties of uniaxial nematic liquid crystals and so it is therefore not surprising that it fails to describe the orientational properties of the splay modulated nematic phase, however, this does highlight the need for an analytic theory of this phase of matter to be developed.

From the first five even orientational order parameters we reconstruct the orientational distribution function (ODF) across the temperature range studied (Fig. 5a). Truncating the reconstruction of the ODF at the 5th $\langle P_{2n} \rangle$ term (ESI,† eqn (S12)) or the sixth f_{2n} term (ESI,† eqn (S13)) gave essentially identical results. The use of higher order parameters (*i.e.* $\langle P_8 \rangle$, $\langle P_{10} \rangle$) allows finer detail to be resolved in the ODF which may otherwise be lost through truncation effects. In both the nematic and splay nematic phases the ODF is (to a first approximation) Gaussian with its maxima at $\beta = 0^\circ$, indicating that in terms of orientational order the N_S phase is locally similar to the preceding nematic (Fig. 5b). As would be expected, we find the FWHM of the ODF decreases as a function of temperature, with a small discontinuity at the N_S -N transition (Fig. 5c). The change in orientation from one molecule to its nearest neighbours that results from the splay modulation is therefore small enough that it is not observable

Fig. 5 (a) Contour plot of the orientational distribution function (ODF) as a function of reduced temperature, where the white dashed line indicates the N_S -N transition temperature. (b) Plot of the ODF of RM734 at five temperatures – dashed lines correspond to the nematic phase, solid lines correspond to the splay-nematic phase. (c) Plot of the HWHM of the ODF as a function of reduced temperature – the dashed line corresponds to the N_S -N phase transition.

by WAXS. The implication is that the periodicity of the N_S phase is large rather than being of the order of a few nanometers as is the case with the N_{TB} phase.

We also studied the orientational order of an analogue of RM734 used in this work in which the nitro group is replaced with a nitrile, in this manuscript we refer to this material as 'RM734-CN' and it has the phase sequence Cr 173.2 N 200.4 Iso. RM734-CN does not exhibit the splay-nematic phase, the temperature dependence of the first four even $\langle P_n \rangle$ order parameters is typical of that of a nematic phase, and the discontinuity observed at the N_S -N transition for RM734 is absent. Further discussion and data are given in the ESI.† The behaviour of the orientational order parameters at the N_S -N transition appears to be unique, and is distinct from other presently known modulated nematic phases.^{7,8} Measurement of the orientational order parameters by WAXS – coupled with the absence of Bragg scattering in small-angle X-ray scattering (SAXS) to confirm a positionally disordered phase – could be considered diagnostic of the splay nematic phase, and therefore provides a means to identify of this phase of matter.

Conclusions

Wide-angle X-ray scattering experiments have been used to probe the orientational order in the nematic (N) and splay nematic (N_S) phases of the liquid crystalline material RM734. The N_S phase displays a slightly greater degree of orientational order than the classical nematic phase, with a discontinuous increase in the first four even $\langle P_n \rangle$ order parameters at the N_S -N phase transition, whereas $\langle P_{10} \rangle$ was found to be effectively zero at all temperatures. Reconstruction of the orientational distribution function (ODF), and the lack of off axis correlation peaks indicates that the change in orientation between two neighbouring molecules that results from the splay modulation of the N_S phase is small, too small to be measured by WAXS. This suggests that the periodicity of the splay-nematic phase, at least in RM734, is larger than the few tens of nanometers envisioned originally.¹¹
