BACKGROUND: Emotional distress is common in cancer patients. This study aimed to describe, in the year after a cancer diagnosis: the incidence of anxiety, depression and excessive alcohol use; the pattern of these diagnoses and treatment over time; and the nature and duration of the prescribed treatment.

METHODS: A matched case–control study was conducted using routinely collected primary care data from 173 Scottish general practices. A presumptive diagnosis of emotional distress (anxiety, depression and/or excessive alcohol use) was based on prescription data or diagnostic code. Prescriptions for psychotropic drugs were described in terms of drug class, volume and treatment duration.

RESULTS: In total, 7298 cancer cases and 14596 matched-controls were identified. Overall, 1135 (15.6%) cases and 201 (1.4%) controls met criteria for emotional distress (odds ratio 13.7, 95% confidence interval 11.6–16.1). Psychotropic drugs were prescribed in the 6 months following initial cancer diagnosis for 1066 (14.6%) cases and 161 (1.1%) controls. The volume and duration of anxiolytic and antipsychotic prescribing was significantly different between cases and controls.

CONCLUSION: This study quantified the higher incidence of new emotional distress in cancer patients in the first year post diagnosis. Clinicians should be aware of the possibility of emotional distress at any time in the year after cancer diagnosis.

Keywords: cancer; anxiety; depression; incidence; primary care; case–control study

Depression and anxiety are common in patients with cancer (Massie, 2004; Sharpe *et al*, 2004; Vahdaninia *et al*, 2010), may occur and be diagnosed at any stage of the cancer journey (Miovic and Block, 2007; Hansen and Sawatzky, 2008) and are estimated to affect up to 40% of people with cancer. About 50% of patients with advanced cancer meet criteria for a psychiatric diagnosis if adjustment disorder is included (Massie, 2004). Newly diagnosed alcohol abuse after cancer diagnosis is a further indication of the emotional impact of the condition (Bringmann *et al*, 2008; Yung and Piccirillo, 2008). Both depression and anxiety are amenable to treatment, both pharmacologically and using cognitive behavioural approaches (Strong *et al*, 2008; Deshields and Nanna, 2010; Holland and Alici, 2010; Wein *et al*, 2010).

Although secondary care is largely responsible for cancer-specific treatment such as surgery or chemotherapy, most general and supportive care of cancer patients takes place in primary care (Lewis *et al*, 2009). This is also where the majority of treatment for depression and anxiety takes place (Munoz-Arroyo *et al*, 2006; Hodges *et al*, 2009). While consultation rates for coded depression or anxiety have been reported to be similar to those of the general population in long-term survivors of common cancers in the UK,

there is an increase in the proportion receiving at least one prescription for an antidepressant, indicating increased mental health morbidity (Khan *et al*, 2010). However, it is not clear at which stage of the cancer journey this excess mental health morbidity occurs.

The aim of this study was to describe, in the first year following a cancer diagnosis in subjects without a pre-existing mental health condition: (a) the incidence of three common mental health problems: depression, anxiety and excessive alcohol use, using a combination of prescription data and diagnostic codes; (b) the pattern of these problems and treatment over time; and (c) the nature and duration of prescribed treatment. Throughout this paper, one or any combination of the above three problems is referred to as emotional distress.

MATERIALS AND METHODS

Design

A matched case–control study was conducted, using routinely collected primary care data (<http://www.abdn.ac.uk/pcciu/PCCIU.htm>).

Subjects and setting

Data from 173 general practices in Scotland was obtained from the Primary Care Clinical Informatics Unit (PCCIU), University of

Received 5 March 2012; revised 6 July 2012; accepted 23 July 2012; published online 11 October 2012

Aberdeen. The PCCIU data comprised anonymised extracts from 173 practices, which used the General Practice Administration System for Scotland (GPASS) software (NHS Scotland, Glasgow, UK). The data for this study was obtained by running specified queries against the Microsoft SQL server holding the extracted general practitioners (GP) data and transferring this into a SPSS database (version 18 for Windows, SPSS Inc., Chicago, IL, USA). The study period was 1 April 2005–1 April 2010, and data were available for 1 026 770 patients.

Inclusion and exclusion criteria

Cases were defined as individuals aged 18 years and older with a diagnosis of one of eight cancer types, selected for their high incidence in the UK: breast, colorectal, lung, prostate, upper gastro-intestinal, melanoma (excluding non-melanoma skin cancers), gynaecological and urological cancers (Cancer Research UK, 2011). Controls were matched according to gender, age (5-year age bands) and general practice. Patients with any cancer diagnosis were excluded from the control group. Patients with a diagnosis of depression, anxiety or excessive alcohol use or who had used antidepressants, anxiolytics or medicines for alcohol dependence in the year before the index date, that is, the date of cancer diagnosis for each individual case, were excluded from both the cases and their matched controls.

Subject identification

The GPASS clinical system utilises the READ V2 clinical terminology for the recording of patient findings, diagnoses and procedures. READ codes are a coded thesaurus of clinical terms (<http://www.connectingforhealth.nhs.uk/systemsandservices/data/uktc/readcodes>). READ codes have two versions: Version 2 (v2) and version 3 (CTV3 or v3), which are the basic means by which clinicians record patient findings and procedures in health and social care IT systems across primary and secondary care (e.g., general practice surgeries and pathology reporting of results). READ codes have been in use in the NHS since 1985 and are still widely used in the primary care sector. Scottish primary care exclusively uses Read V2. They are maintained by the UK Terminology Centre. Cross-maps are maintained from the Read codes to the UK-mandated classifications of OPCS-4 and ICD-10 Pathology Bounded Code List. Code sets to identify cancer cases and the diagnoses of depression, anxiety and excessive alcohol use were developed from the Scotland READ V2 browser released in Spring 2010. Prescription of antidepressants, anxiolytics or medicines for alcohol dependence was defined by the British National Formulary (BNF) 59 chapter sections 4.3.1–4.3.4 (antidepressants), 4.1.2 (anxiolytics) and 4.10 (subsection alcohol dependence) (2010).

A 1:2 case-control matching ratio was applied. Hence, each cluster comprised one case and two-matched control patients. The following criteria were then applied (Figure 1). First, cases without sufficient matching control patients were excluded. Second, clusters which included patients with multiple cancer diagnoses at first date of diagnosis were excluded if no clinical evidence was available to identify the first diagnosed cancer thus preventing stratification according to index cancer site. Third, only clusters with an index date earlier than 1 October 2008 were included to allow for 18 months of follow-up data for the outcome assessment. Finally, clusters which included at least one patient who had died before the index date were excluded.

Outcome

The primary outcome was the composite measure of emotional distress (i.e., anxiety, depression and/or excessive alcohol use).

The secondary outcome was the prescription of psychotropic drugs in the first 6 months after the diagnosis of emotional distress. For this secondary outcome we included drugs listed as indicating emotional distress plus those in BNF chapter sections 4.1.1 (hypnotics), 4.2.1 (antipsychotics) and 4.2.3 (anti-manics). For each patient we recorded the type of drug, the total quantity prescribed (expressed as total DDDs (defined daily dose) (WHO, 2010)) and treatment duration.

Data specification

For each patient we extracted data on gender, age, socioeconomic deprivation (seven categories of the Carstairs index (Morris and Carstairs, 1991)), urban/rural status (six-fold classification of the Scottish Index of Multiple Deprivation 2006 at practice level (Office of the Chief Statistician, 2006)), smoking (never smoked, ex-smoker and current smoker according to the latest registration of READ codes) and date of death (if relevant). For cases, data on registration in the Palliative Care Register (an indicator for the cancer stage) was also extracted.

For each prescription in the 6-month follow-up period, we extracted the generic drug name, the date of issue, the strength, the dose and the frequency. Estimated daily doses were translated into DDDs (Burton *et al*, 2012), using the WHO standard values (WHO, 2010). Total duration of treatment in days was calculated by subtracting the date of the last prescription from the date of the first prescription and adding the actual duration of the last prescription. Total DDDs prescribed and duration was calculated per patient for drug groups and subgroups of interest. Liquid preparations (about 1% of the psychotropic drug prescriptions) were excluded from the database as calculations for volume and treatment duration were unreliable. In reporting medication use in patients who met our criteria for emotional distress, we did not attempt to distinguish between use for a primary psychiatric condition or for other indications such as pain (tricyclic antidepressants) or nausea (typical antipsychotics) as this information is not available in the database.

Standard methods of data cleaning and validation were applied. The internal reliability of the data was checked by searching and checking the type of data received and the outliers for each variable.

The North of Scotland Research Ethics Committee was contacted to determine whether formal ethical approval was required for this study. As the data used was anonymous at every stage of the research process full formal ethical approval was not required.

Statistical analysis

Descriptive analyses (frequencies for categorical variables, mean and s.d. for normally distributed continuous data, and median and inter quartile range for non-normally distributed continuous data) were conducted. Demographic characteristics and incidence rates were compared between cases and controls using conditional logistic regression. Odds ratios (OR) and the 95% confidence intervals (CI) were reported. Matched survival analysis (using a stratified COX model) (Cox, 1972) was used to produce Kaplan-Meier graphs to illustrate the timeline of incident emotional distress. The assumption of proportionality was tested and met. Analysis was completed for the time from index date up to 1 year, using death as a censoring variable. The χ^2 test was used to compare the proportions of drugs (and drug groups) and to compare the frequencies of users of psychotropic drugs between cases and controls. When numbers were small, Fisher's Exact test was used instead of the χ^2 test. The Mann-Whitney *U*-test was used to compare the quantity and the duration of prescriptions between cases and controls.

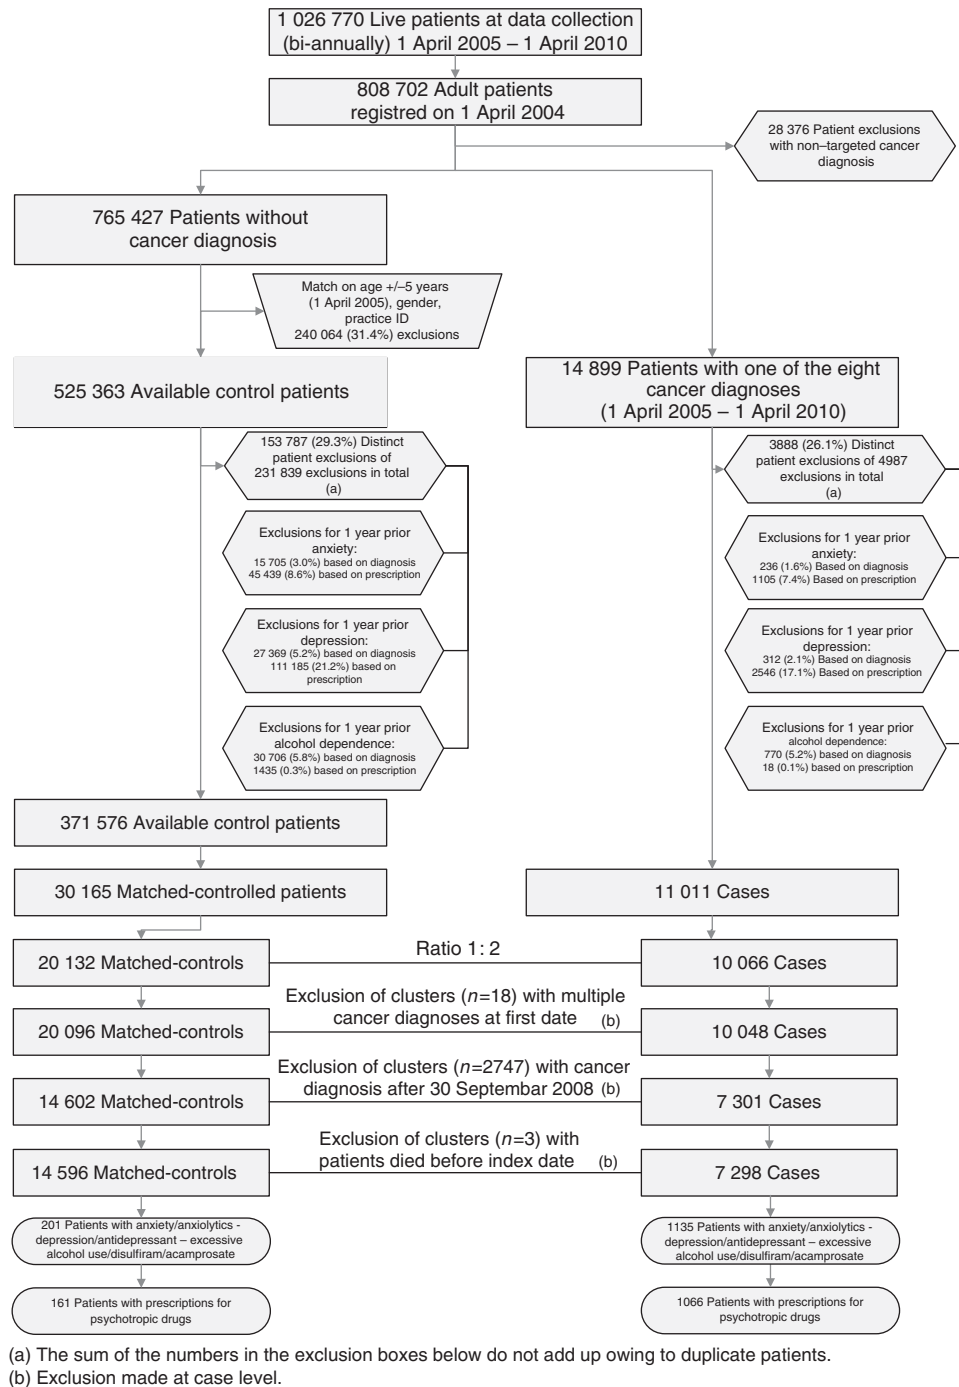

Figure 1 Flow chart of sample.

Data handling and analyses were performed using PASW Statistics 19.0 (Predictive Analytics SoftWare) for Windows (2010, SPSS Inc.). STATA 11 (2009, STATA, TX, USA) was used for the conditional logistic regression and the stratified COX model.

RESULTS

Sample

Based on the inclusion and exclusion criteria and the subject identification process, 7298 cancer cases and 14 596 matched-controls were identified (Figure 1). Sample characteristics are

summarised in Table 1. Half of the sample was female (50.7%). The mean age was 67.4 years. No statistically significant differences between cases and controls were observed for deprivation. The proportion of ex-smokers (OR 1.57 (95% CI 1.48–1.68)) and smokers (OR 1.35 (95% CI 1.24–1.46)) was significantly higher among cases. A higher proportion of cases died within 12 months (OR 99.5 (95% CI 47.1–210.3)) and within 18 months (OR 52.1 (95% CI 31.6–85.9)) of index date.

Incidence of emotional distress

Overall, 1135 (15.6%) cases and 201 (1.4%) controls were identified with emotional distress within 1 year following the index date

Abbreviations: CI = confidence interval; OR = odds ratio; s.d. = standard deviation. ^aCases: patients diagnosed with cancer during the period 1 April 2005–30 September 2008 with no history of mental health problems in the year before cancer diagnosis; controls were age, gender and practice-matched patients with no cancer diagnosis in their medical history. ^bNo statistics reported as age, gender and practice (urban/rural data is on practice level, not on patient level) were used for matching.

(Table 2). The overall OR for emotional distress between cases and controls was 13.66 (95% CI 11.59–16.11). When comparing cases with controls, the OR for the incidence of anxiety and/or anxiolytics was 14.32 (95% CI 11.23–18.26) (537 (7.4%) cases vs 84 (0.6%) controls); for depression and/or antidepressants 13.84 (95% CI 11.24–17.03) (713 (9.8%) cases vs 112 (0.8%) cases); and for excessive alcohol use and/or disulfiram/acamprosate 4.07 (95% CI 2.57–6.46) (55 (0.8%) cases vs 27 (0.2%) controls).

The Kaplan–Meier graphs (Figure 2) illustrate the time from the index date to identification of emotional distress. The figures show that during the 1-year period post index cancer diagnosis there was no specific time point at which indicators of emotional distress, as previously defined, were recorded.

Psychotropic drug prescriptions in the 6 months after the diagnosis of emotional distress

Psychotropic drugs were prescribed for 1066 (14.6%) cases and 161 (1.1%) controls in the 6-month period after initial diagnosis (Table 3). Cases were prescribed more psychotropic drugs ($P < 0.001$) and more psychotropic drug groups ($P < 0.001$). The majority of the controls used one psychotropic drug (80.7%) or drug group (85.1%) compared with 61.8% and 64.1%, respectively, among cases. Of the individuals prescribed psychotropic drugs,

prescriptions for antidepressants were issued in 64.9% ($n = 692$) vs 62.7% ($n = 101$) controls ($P = 0.589$), anxiolytics in 46.5% ($n = 496$) of cases vs 37.9% ($n = 61$) of controls ($P = 0.040$), hypnotics in 22.7% ($n = 242$) vs 7.5% ($n = 12$) ($P < 0.001$), antipsychotics in 8.8% ($n = 94$) vs 6.2% ($n = 10$) ($P = 0.268$) and anti-manic drugs in 0.9% ($n = 14$) vs 1.1% ($n = 2$) ($P = 1.000$).

The total prescribing volume and duration of psychotropic drug prescriptions in the 6-month follow-up period is listed in Table 4. These values were significantly different between the cohorts for anxiolytic and antipsychotic drugs. Anxiolytics were prescribed in greater volume ($P = 0.017$) and for a longer time ($P = 0.003$) in cases. The opposite was observed for antipsychotic drugs, which were prescribed in smaller volumes ($P = 0.041$) and for shorter periods ($P = 0.002$) in cases. Hypnotic, antidepressant and anti-manic prescriptions were comparable between cases and controls.

DISCUSSION

Summary of findings

Patients diagnosed with cancer were at least 10 times more likely than matched controls to be diagnosed with emotional distress in the year following a cancer diagnosis. The first coded diagnosis or

Table 2 1 year incidence (and proportion of affected individuals identified by diagnostic code, prescription or both) of diagnosis of emotional distress with ORs and the number of emotional distress categories per patient

prescription occurred evenly throughout the year after diagnosis, with no discernible peak to indicate a time of particular vulnerability or recognition. Treatment was mainly of brief duration indicating that it might have been more symptomatic (e.g., hypnotic or antipsychotic prescription) rather than diagnosis-specific (e.g., sufficient dose and long duration of antidepressant prescription).

Strengths and limitations

This study quantifies the primary care recorded incidence and pattern of emotional distress in the year following a cancer diagnosis. The data were derived from a large database of routine general practice data capturing comprehensive information on prescriptions. Matching by age, gender and location removed the effects of these confounders. We were able to study newly incident emotional distress by excluding, from case and control groups, patients with a relevant diagnostic code or treatment in the year before their index date. We used detailed prescribing data to estimate treatment dose and duration and this included two measures of treatment duration – one based on actual dates of issue and one based on the sum of the durations of actual regimens. We found no meaningful difference in duration by these two methods (results available from the authors on request). Our matched control group had an incidence of 0.6% for anxiety/anxiolytics and 0.8% for depression/antidepressants, which is consistent with other studies (Rait *et al*, 2009; Martin-Merino *et al*, 2010). These figures support the validity of our methods and representativeness of the GPs and patients included in the data set.

There are several limitations with this study. Firstly, GPs do not record diagnostic codes for all patients they see or treat for common mental disorders. It is possible that GPs saw more patients with emotional distress than were identified by diagnostic codes, particularly patients who did not receive drug treatment. Also, some individuals may have received psychological support from non-general practice providers or organisations. Moreover, in mental health research, diagnoses should be supported by structured clinical interviews, such as the Structured Clinical Interview for DSM-IV (First *et al*, 1996). Such interviews were

unlikely to have been conducted by GPs. Secondly, while GPs in Scotland issue prescriptions through practice computer systems and the volume of prescribing is reliable, the indication for treatment is not available and can only be inferred. Our data included tricyclic antidepressants, which are commonly (up to 70%) prescribed for non-psychiatric problems such as pain management (Patten *et al*, 2007; Lockhart and Guthrie, 2011). Some antipsychotics (e.g., prochlorperazine) might also be prescribed for nausea (Roffman and Pirl, 2003). As such, it is likely that our figures overestimate the incidence of drug treatment for emotional distress. Thirdly, we excluded patients with pre-existing emotional distress. Therefore, our results may underplay the burden of emotional distress in people with cancer, as a cancer diagnosis may exacerbate underlying psychological morbidity. However, our rates indicate the considerable burden of 'new' emotional distress following a diagnosis of cancer.

Only very small numbers of newly incident cases or treatment for alcohol-related disorders were identified and no meaningful interpretation could be made of these. Although this study described the cases identified or treated by their GP, it does not include those who were not. Finally, a higher case:control matching ratio (for example, up to 1:5) may have given us slightly higher statistical power compared with the 1:2 ratio achieved. The size of the database population did not permit this.

Relationship to other research

Prevalence rates of depression in cancer patients previously reported from cross-sectional studies have been estimated to be up to 40% (Massie, 2004). These increased rates in cancer patients were found irrespective of cancer site (Miovic and Block, 2007). Similar prevalence rates for anxiety have been described in cancer patients. Our findings showed an overall incidence rate of emotional distress of 15.6% (9.8% for depression and 7.4% for anxiety) within 1 year following cancer diagnosis, which was much greater than in the non-cancer population. It appears that GPs are identifying and addressing emotional distress in people with cancer, but no conclusions can be drawn from our data on whether all incident cases were identified. Our results differ from the

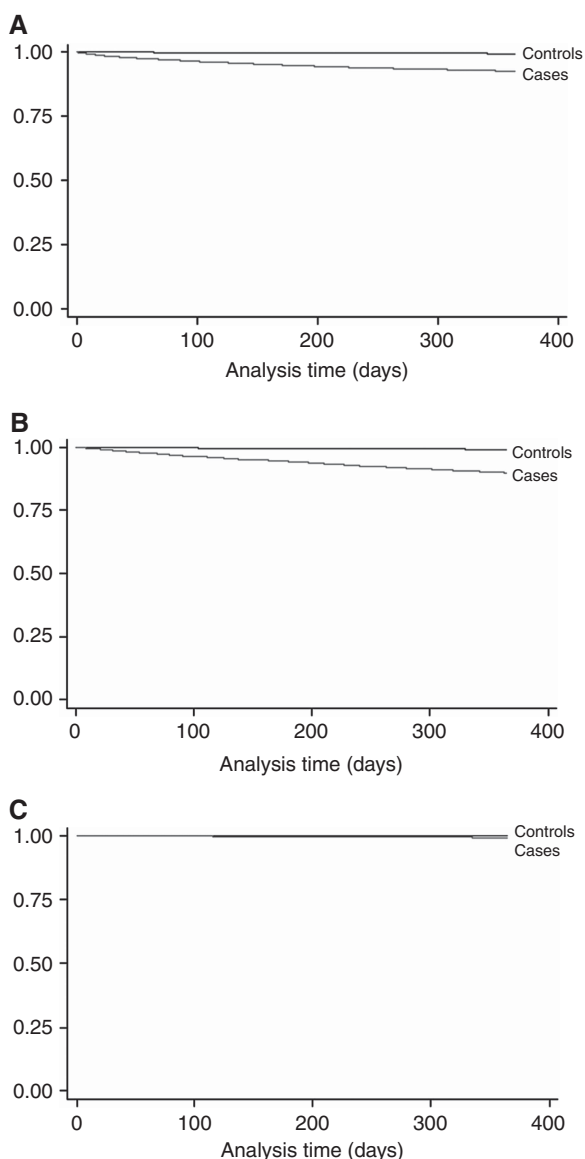

Figure 2 Kaplan–Meier graphs illustrating the proportion of patients at each time in 1 year after the index date with a first diagnosis and/or prescription for (A) anxiety/anxiolytics, for (B) depression/antidepressants and for (C) alcohol/acamprosate/disulfiram; the time to diagnosis and/or prescription is expressed in days.

case–control study by Khan *et al* (2010), which showed no significant increase of depression and anxiety in those surviving for 5 years after a cancer diagnosis. The longer time since diagnosis used in Khan’s study may have obscured rises in emotional distress in the immediate post-diagnostic period which subsequently resolved at the time of data collection. Furthermore, the current study included patients who did not have such a good prognosis (study period covers up to 1 year after cancer diagnosis) as all cancer cases in the study of Khan (survival for at least 5 years).

Table 2 shows a small overlap between diagnostic codes and psychotropic drug prescriptions. The majority of individuals identified with emotional distress received a psychotropic drug prescription without a diagnostic code. This might be due to under-coding of mental health disorders in patients’ medical records. Contextual and psychosocial circumstances might

Table 3 Number of different psychotropic drugs per patient, different psychotropic drug groups taken per patient and users within each drug group taken by patients identified with a diagnosis of emotional distress and with a psychotropic drug prescription in the 6 months after initial diagnosis and/or prescription ($n = 1227$)

influence a GP’s decision to prescribe an antidepressant but not record a diagnostic code for depression. For example, GPs might omit these codes believing significant distress in the face of a cancer diagnosis to be ‘normal’ despite warranting treatment. Alternatively, codes may be omitted to avoid stigmatising patients or avoid a further diagnostic burden (Rait *et al*, 2009; Burton *et al*, 2012). The present data provide evidence that GPs are identifying and managing emotional distress but not always recording it as a diagnosis. In a time of increasing performance review, audit, and guideline-driven care, there is a need for universal diagnostic coding of all encounters. Our data suggests that the fixed terms available within the READ V2 hierarchy may not always fit the requirements of GPs in recording details of a consultation. Clinicians may prefer free text (not assessed during this study) or perhaps new codes appropriate to the cancer context should be created?

Patients at later stages of cancer, who have more physical symptoms or at specific times during their trajectory (such as diagnosis, suspicious symptoms and beginning and starting treatment) are at increased risk of distress (Madden, 2006). The steady development of emotional distress throughout the first year following diagnosis described in our study might be explained by our heterogeneous sample with respect to cancer site, disease stage and treatment.

The duration of anxiolytic prescriptions followed the clinical guideline to use benzodiazepines for short term relief (2–4 weeks only) (NICE, 2011). The drug group ‘hypnotics’ are not licensed for long-term use but the median of 55 days (8 weeks) of use among cases tended to exceed guideline recommendations of a

Abbreviations: IQR = inter quartile range; DDD = defined daily dose. ^aFor each prescription the strength, the dosing and the frequency were used to estimate the daily dose. Estimated daily doses were translated into DDD using the WHO standard doses (WHO, 2010). ^bDuration was based on the calculation of the number of days between issue date of first and last prescription, and added with the duration of the last prescription, in days. Statistically significant results ($P < 0.05$) are indicated in bold.

few (2–4) weeks (2010). Clinical guidelines recommend the use of antidepressants for 6 months after remission of depression (NICE, 2009). The median duration of antidepressant prescribing in this study was 2 months. The number of patients with anti-manic and anti-alcohol medicines was too low to draw any conclusions.

Implications for practice, policy and research

The small overlap of diagnostic coding with psychotropic prescribing and the shorter antidepressant treatment duration than that recommended in clinical guidelines might possibly point towards under-recognition and/or under-treatment of major depressive disorders in this patient population. The absence of a clear temporal pattern of incident emotional distress in the cancer trajectory indicates a need for clinician vigilance throughout the first year from diagnosis. All health professionals, in primary and secondary care, should be alert to emotional distress in patients with cancer and ensure psychological health is discussed and treated. Specific reference to the management of emotional distress should be incorporated into follow-up guidelines for cancer management.

Policy makers should address the need for improved coding of diagnosis and management of emotional distress in newly diagnosed cancer patients. While retaining an option for free text for clinical purposes, GPs might be encouraged to use a flexible coding system in which symptom codes for distress, such as low mood, are used until patients clearly meet criteria for a major depressive disorder. Another alternative would be to include a code such as 'distress related to cancer diagnosis'.

Further research is needed to explain the small overlap between mental health diagnostic codes and psychotropic prescriptions and the lower use of mental health diagnostic codes in general. Data linkage with secondary care systems would provide more

comprehensive information about mental health service use by cancer patients. Moreover, studying the patient perspective in identifying and managing emotional distress after cancer diagnosis would enable these current results to be put in context. Finally, larger numbers of patients would be needed to study the extent of excessive alcohol use in this population.

CONCLUSIONS

Cancer patients are at substantially higher risk of emotional distress in the year following their cancer diagnosis. The pharmacological treatment of emotional distress in primary care tends to involve low doses of short duration. Incidence of emotional distress was evenly spread throughout the year after diagnosis with no time of particular vulnerability. Clinicians should be vigilant for emotional distress in patients during the first year following cancer diagnosis.

ACKNOWLEDGEMENTS

We would like to thank Fiona Chaloner and Katie Wilde for extracting the database. The data contained herein were provided by the Primary Care Clinical Informatics Unit (<http://www.abdn.ac.uk/pcciu/PCCIU.htm>) at the University of Aberdeen. The views in this publication are not necessarily the views of the University of Aberdeen, its agents, or employees. Dr Amalraj Raja is thanked for the statistical support. Franciska Desplenter received a travel grant from the KU Leuven 'Fonds Apotheker en Mevrouw Ysebaert-Devos' for the period January–March 2011 and from FWO Vlaanderen (Reference V4.248.11N) for the period April–December 2011.
