Abstract

The distributions of methylene and ether bridges have been shown to impact the mechanical properties of phenolic resin. This work demonstrates the ability of the novel SEM based technique, Secondary Electron Hyperspectral Imaging (SEHI), to characterise and map methylene and ether bridges within phenolic resin at the nanoscale.

Main Text

Phenolic resins are a group of the most versatile polymers ever formulated. Although they were first produced around 1907 and were consequently one of the first polymers commercially available, they have been in constant development and use ever since and are widely used in various applications [1]. A recent review article highlighted the deployment prospects of phenolic resin and evaluated where future research should focus to further increase and improve the potential of phenolic resins for future industrial applications [2]. The article highlighted that improving phenolic resin's heat resistance and reducing brittleness are key enablers to future deployment opportunities. Demands from the aerospace industry and other industries with challenging environmental conditions raise the requirement to improve the long-term high-temperature oxidation resistance of phenolic resin [3]. Historical studies have

long establishing how novel synthesis interventions can augment the material's properties by altering the macromolecular structure of phenolic resin [4] [5].

Research focused on increasing phenolic resin's thermal stability with the aim of producing 'tougher' forms of phenolic resin has shown success by optimising the distribution of voids in the resins [6]. Alternative approaches to addressing known 'brittleness issues' within phenolic resin [7] [8], have also shown success through the inclusion of substances such as, rubber, glass fibres and thermoplastic resins [9][10][11].

Further work towards delivering 'tougher' phenolic resins has investigated altering the polymer network of the resin by changing the bonding ratios of methylene and ether bridges [12][13]. This work has identified improvements to the efficiency of the resin's production process which also mitigate environmental concerns of current practice. It has been observed that the quantity of ether bridges forming within the resin increases when the F:P (formaldehyde: phenol) ratio increases and, depending on processing conditions, high numbers of ether linkages [14] reduce the strength of the cured resin [15]

Despite the improved functionality of such resin more efficient and potentially greener ways of improving toughness of phenolic resin have come from studies targeted at altering the polymer network of phenolic resin by changing the bonding ratios of methylene and ether bridges have also delivered tougher materials [12][13]. The proportion of ether bridges rises with increases in the F:P (formaldehyde: phenol) ratio, with an excessive amount of ether linkages [14] reducing the strength of the cured resin [15]. It is important to note that processing conditions are also influential on the final strength of the cured resin.

Fast acting catalysts reduce the resin's curing time and impart "void like" structures [6]. This is in contrast to phenolic resins that are required to be produced free from voids which typically require intensive curing processes using multiple heating cycles.

Such processes carry the disadvantage of slower curing cycles that create extra formaldehyde emissions. Future optimisation of phenolic resin properties requires an understanding of how these processes affect the material's structure at the nanoscale. The ability to map chemical bonding changes at the nanoscale would enable polymer scientists to better construct and optimise processes' designed to alter the bonding ratios of methylene and ether bridges observed in phenolic resin.

Secondary Electron hyperspectral imaging (SEHI) is a novel technique built on SE spectroscopy and has been used for characterising the surface chemistry of innovative polymeric biomaterials [16]. A scanning electron microscope's (SEM) ability to detect secondary electrons (SEs) emissions from a material sample is the basis for SEHI. A series of images collected from selected SE energy bands is constructed to form the SEHI images stacks. This is in contrast to a standard SEM which assembles a single image with SEs of all energies contributing to it. SEHI delivers novel characterisation insights by creating a wide-ranging SE spectral representation of the sample material. A number of research studies have demonstrated SEHI's effectiveness including; molecular orientation of organic electronic devices [17], semi-crystalline polymer mapping and natural materials nanostructure variations [18] but has not yet been applied to the mapping of ether or methylene bridges.

This study focuses on analysing the chemical bonding structure of a form of phenolic resin, PR382. PR382 has recently been produced [6] with the design aim of minimising losses in desirable mechanical properties which occur as a consequence of using typical current resin production processes. This is achieved by substituting a new faster curing, more cost effective

and environmentally friendlier fast curing cycle based production process. Analysis of phenolic resin requires the ability to map the chemical bonding distribution within the resin through the application of the SEHI technique. The emphasis of this study is mapping and showing sensitivity to specific bonding mechanisms that are present within the phenolic resin sample post synthetic intervention, as an example of how the SEHI technique can provide an enhanced understanding of micron – nano scale structures. This work establishes that the voids created as the phenolic resin cures in response to a slow acting acid catalyst, are a focus for a high level of CO bonding attributable to ether bridge formation around the voids sites.

Materials and Methods

Materials

In this study, the resole commercial phenolic resin Cellobond J2027X pre-polymer was used (supplied by Caleb Technical Products Ltd., UK). This kind of resin is usually available as a water-based controlled-viscosity resin, which can be cured either with the application of heat only using long cure cycle (3-4 days) or with the use of a strong acid catalyst, short cure cycle (3 h) at low temperature ($\sim 60^{\circ}\text{C}$). It is suitable for the fabrication of fibre composites by hand layup and resin transfer molding. Catalyst (Cellobond Phencat 382), supplied by the same company (Caleb Technical Products Ltd., UK), was used in this study. Phencat 382 is a relatively slow action acid catalyst (working life $\sim 4\text{h}$), which is activated at low temperature, typically $60\text{--}80^{\circ}\text{C}$. It is an acid-based catalyst consisting of, C3-9-alkyl esters (75–90%) and phosphoric acid (10–25%) by weight. A short cure cycle was selected where the resole phenolic resin was initially mixed with slow action acid catalyst (Phencat 382) then decanted into the PTFE mold to be placed in an autoclave for polymerisation. The catalyst ratio was 5 wt% of the resin. Phenolic resin samples were fractured to allow for analysis of the cross-section of the material.

Methods

Imaging – Phenolic resin samples were fractured and placed on a carbon tab on an aluminium stub ready for SEM imaging. Observation of the fracture surface morphology of the flexural strength samples (PR382) was performed using a Scanning Electron Microscope (FEI Nova Nano 450 SEM). The PR382 samples were not subject to deposition of conductive coating, in contrast to usual polymers SEM analysis practice. To avoid surface charging and consequent damage to the sample a low accelerating voltage (1 kV) with typical vacuum pressure of 10^{-5} mbar at a working distance of 3 mm was applied. An Everhart-Thornley Detector (ETD) for low magnification images and a Through Lens Detector (TLD) for high magnification images were used for the collection of SE images.

SEHI Acquisition and Image Processing - The FEI Nova Nano 450 SEM is provided with a through lens detector which includes a voltage controlled deflector electrode. The deflector electrode channels the signal into the SE detector. The deflector electrode is set to a predetermined deflector voltages and an image is generated for each deflector voltage (More detailed information provided in SI). Spectra and hyperspectral images are acquired through post-processing of such image series. Stage bias experiments have been performed to allow energy calibration of this process through experiments [19][17]. Fiji software was utilised to perform image processing [20]. Histogram and spectral off-set normalisation [21] has been applied retrospectively to optimise all images for brightness and contrast, and to limit the effects of differing sample work functions. The work function of a material is the minimum energy required to remove an electron from the solid to outside the solids surface within a vacuum. Once S-curves have then been obtained they are differentiated to produce the SE curves. Component analysis was then performed to image stacks utilising non negative matrix factorization (nmf) to isolate components of interest.

Theoretical grounds of Secondary Electron Spectroscopy (SES) - A typical SE spectra is a View Article Online
DOI: 10.1039/D0PY01220C

plot of the number of electrons detected within a specific energy range. Each chemical functional group produces a set of characteristic peaks in the SE spectra (SES) (16). Based on knowledge of functional groups, material properties can also be inferred from the measurement of the kinetic energy and the number of the emitted SE's in some circumstances. SEHI can be summarised as a technique that is responsive to surfaces and is capable of imaging beam sensitive materials by resolving chemical, compositional and structural properties at the nanoscale level – depending on the energy range used for imaging. SEHI is proposed as an effective microanalysis tool for nanostructured polymers with the ability of mapping chemical functional groups of particular interest. More information on the theoretical grounds for probe-sample analysis and SES are given in the SI.

Results and Discussion

To illustrate the chemical bonding variations within PR382, SE spectra given in figure 1 represent spectra captured from three different areas (1, 2 and 3) across the cross-sectioned material. Each area's SEM field of view is included to show the exact region of analysis. Area 3 differs by virtue of its increased magnification which allows analysis of a single void site of interest.

Figure 1 - Secondary electron spectra with accompanying SEM images for PR382 Area 1, 2 and 3 highlighting SE regions identified as associated with functional group emissions. Area 1 & 2 HFW = 30 μm whereas Area 3 HFW = 25 μm .

Previous studies have isolated the energy range of 1.4 – 2.3 eV to the molecular order of polymers [22]. An increase in peak intensity in this range indicates an increased molecular order, indicative of the material being more crystalline. Areas 1 & 2 show a higher intensity level when compared to Area 3. Area 3 is therefore disordered, as we do not observe any sharp peaks within 1.4 – 2.3 eV range. These observed differences are due to Areas 1 and 2 both encompassing a greater density of cured cross-linked networks than that of Area 3 which focuses on a singular void site.

Figure 2 –A) A graph which shows the ratio of OH and CO functional groups for Area 1, 2 and 3 after all area spectra were normalised to their CH emission peaks. B) Displays the possible cross-linking mechanisms (Methylene and ether bridge formation) within phenolic resin.

SE spectra analysis can provide for comparisons to be drawn regarding crosslinking networks. The SE emission captured in this study for Areas 1 and 2 exhibited a greater SE emission in the energy range associated with CH vibrations and -OH groups [23][16][24] when compared to that of Area 3. The increase of CH₂ and -OH formation in this polymer system indicates the presence of methylene bridges. Results obtained from the raw SE spectra display an increase in CH vibrations. The data given in figure 2 A, shows an increase in -OH groups (when all areas are normalised to CH peak emission). These two results provide evidence to support the conclusion that Areas 1 and 2 contain a greater density of methylene bridges than Area 3.

All three areas show emissions within the SE emission region associated with C-O bonding. C-O bonding in Area 3 displays the strongest emission ratios (when all areas are normalised to their respective CH emissions peak) compared to Areas 1 and 2. As C-O bonding in phenolics is related to ether bridges (See figure 2B), Area 3 possesses a large density of ether bridges compared to Area 1 and 2. Figure 2 B shows the chemical bond formation of the two common types of crosslinks present within phenolic resin. Figure 2 B (1) depicts the various example structures of methylene bridges formation which is the most common form of crosslink with phenolic resin networks [15]. Figure 2 B (2) depicts the formation of ether bridges which are less commonly found within phenolic resin.

From the SE spectra results it can be assumed that this is consistent with Areas 1 & 2 having a greater matrix (areas away from voids) concentration in the analysed field of view which will consequently have more (CH₂, -OH) linked methylene bridges. Thus the SE spectra results show that areas 1 and 2 contain a higher density of methylene bridges than Area 3 and also display a greater molecular order SE peak than Area 3. Methylene bridges possess a shorter bridging length when compared to that of ether bridges, which has a greater number of atoms between its phenyl rings. Therefore, phenolic resin with a greater ratio of methylene bridges to ether bridges would present a more ordered structure by virtue of ether bridges having a higher number of rotational degrees of freedom and being inherently flexible (See figure 3). The difference in chain length could also explain why there is a higher concentration of -OH detected as the phenyl rings appear more densely packed.

Figure 3 – The rotational degrees of freedom observed in ether bridges

Various techniques have already shown that phenolic resin contains different ratios of methylene and ether bridges and this study's results above are not novel in that respect. However, by building on SE emission ranges obtained from the resulting SE spectra, it is now possible to use SEHI to map ether and methylene bridge spatial distributions on different length scales as demonstrated in Figure 4 (and SI1).

Figure 4 - SEHI images generated from the component analysis of PR382 mapping CO bonding (indicating ether bridge distributions). With the stronger emission intensity showing greater CO bonding. SEHI images are overlaid with grayscale standard SE images (integral over all energy ranges) of PR382.

Figure 4 shows SEHI images overlaid on standard SEM images to show the distribution of CO bonding. While the standard SEM image does not allow to determine the origin of the

contrast associate with the voids, SEHI data enable component analysis to be performed on image stacks utilising non-negative matrix factorization (nnmf) to isolate components of interest (See SI 1, 2 & 3). The nnmf process gives a number of components which are derived in relation to the SE emission peaks of interest. Of particular importance to phenolic resin, nnmf isolated a region around 5 – 5.5 eV which has previously been shown to be a response to CO bonding [16] [24]. Therefore, this technique provides SEHI with the ability to map where ether bridges exist within the resin. SEHI images observe CO bonding emission to be most prominent around the edges of void sites. The mechanism of how ether bridges form around these voids is a subject for debate. The authors in this instance propose two potential mechanisms to be involved, but future work is required to fully understand this reaction.

One mechanism is based on the curing reaction of the resin itself: the structural inhomogeneity of “Water/formaldehyde bubbles” is associated with density fluctuation that is related to crosslink density distributions that have been reported to exist within phenolic resin [25]. In this case we propose that the inhomogeneous distribution of crosslinks can cause void trapping. As the water/formaldehyde bubbles form and migrate within the autoclave to the surface of the material, it is postulated that they become trapped by ether bridges developing around the edges of the voids. It has been long established that increasing the F:P molar ratios favours the production of ether bridges [14]. As the voids sites predominantly contain water and formaldehyde, both by-products of previous crosslink reactions, it is suggested that voids sites have an increased localised F:P ratio. This relationship would explain the ether bridge configuration around void sites as their formation is the preferred crosslink route [15].

View Article Online
DOI: 10.1039/D0PY01220C

Figure 5 – Water/Formaldehyde bubble migration due to material density formation.

A proposed alternative mechanism is associated with the possibility that there is a preferred route for the water/formaldehyde bubbles take when attempting to leave the resin during curing [26]. As the phenolic resin cures, the bubbles will leave the material by following a path of least resistance and therefore their migration will follow the least dense regions within the resin (See figure 5). Consequently, the voids will be concentrated away from areas of higher density molecular structures (strong methylene bridge content) and towards less dense molecular regions (strong ether bridge content). This is as a result of ether bridges containing

a greater number of atoms between the anchoring phenol rings with intramolecular forces known to decrease rapidly with distance. Prior modelling studies have revealed that mass density fluctuations within phenolics are due to the inhomogeneous reactions described previously [27]. These studies have observed density variations at the nano-scale but have encounter difficulties modelling at larger length scales. SEHI, being inherently multiscale in analysis, confirms the observed density variations in phenolic resin at the nano-micron scale and also provides evidence that they are dependent on inhomogeneous crosslinking reactions. Figure (SI4) supports the proposal that such variation observed in molecular density and crosslinking reactions does translates to large variations being exhibited in the nano-structural hardness of the resins.

Conclusions

The presented SEHI analysis and related SE spectra provide compelling evidence that a greater prevalence of C-O bonding exists in close proximity (~ 50 nm) to void sites than the typical distribution observed within the matrix. This result can be explained to be the consequence of an increased incidence of ether bridges observed at such void sites. SEHI further revealed local variations in crosslinking and molecular order and functional groups (CH, OH) across the resin. Based on the demonstrated capability, SEHI is considered to be an ideal analysis tool with the capacity to isolate local variations in reactant remnants, such as formaldehyde, within phenolic resin.
