ABSTRACT

Introduction: Brentuximab vedotin (BV)-CHP is the new standard regimen for first-line treatment of systemic anaplastic large cell lymphoma (sALCL). We undertook a retrospective analysis of consecutive patients diagnosed with

sALCL, treated in routine practice, to serve as a benchmark analysis for comparison BV-CHP efficacy in routine practice.

Methods: Patients aged 16 years or older with sALCL treated in seven UK and Australian centres and from 14 additional centres from the UK Haematological Malignancy Research Network database ($n = 214$). Treatment allocation was clinician choice and included best supportive care (BSC). Main outcomes were time to treatment failure (TTF) and overall survival (OS).

Multivariable analysis for predictors of both TTF and OS was also undertaken.

Results: The median age 52 years (range 16–93), 18% ECOG \geq 3 and 40% of cases were ALK positive. CHOP (cyclophosphamide, adriamycin, vincristine, prednisolone) was employed in 152 (71%) of patients and CHOEP (CHOP + etoposide) in 4% of patients. For CHOP-treated patients overall response rate (ORR) was 65% and complete response (CR) 47%. Only 9% of patients underwent autologous stem cell transplant (ASCT). With 57 months median follow-up, 4-year TTF and OS were 41.2% (95% CI 33.1–49.1) and 58.9% (95% CI 50.3–66.5) respectively. Multivariable analysis showed ALK+ status was independently associated with superior TTF (HR 0.36, 95% CI 0.21–0.63) but not OS (0.44, 95% CI 0.18–1.07).

Discussion: We present a retrospective analysis with mature follow-up of one of the largest multicentre populations of sALCL available, comparable to similar large retrospective studies. ALK status remains a strong predictor of outcomes.

Conclusion: These data serve as a robust benchmark for BV-CHP as the new standard of care for sALCL. Similar real-world evidence with BV-CHP will be desirable to confirm the findings of ECHELON-2.

Keywords: Adcetris; Autologous stem cell transplantation; Brentuximab vedotin; CHOEP; CHOP

Key Summary Points

We report one of the largest observational sALCL studies demonstrating CHOP as the preferred treatment regimen for sALCL. CHOP demonstrated slightly inferior outcomes in the real-world setting when compared to clinical trial data.

Low rates of high-dose therapy (HDT)-ASCT performed in CR1 were observed in ALK-negative patients with sALCL in line with current controversy of the true benefit of this strategy.

ALK status remains a significant and strong predictor of outcomes in sALCL, with a 64% reduction in the risk of death and non-significant 56% reduction in risk of treatment failure for ALK+ patients.

We also describe the real-world outcomes of BV in the relapse setting, which compare unfavourably with results from pivotal trials, suggesting a degree of patient selection.

INTRODUCTION

Peripheral T cell lymphomas (PTCLs) represent 10–15% of non-Hodgkin lymphomas and comprise 23 different entities [1]. Anaplastic large cell lymphoma (sALCL) is a relatively rare subtype of T cell non-Hodgkin lymphoma [2], with a prevalence of 12.1% among PTCLs entities [1]. sALCL is characterized by ALK protein expression in 40–50% of systemic cases [3]. Cyclophosphamide, adriamycin, vincristine, prednisolone (CHOP) has been the standard of care for frontline sALCL for decades, delivering 5-year overall survival (OS) rates of 70–81% for ALK-positive cases [3–5] and 42–49% for ALK-negative cases [4–6]. The International T cell Project has reported results of 235 ALK-negative patients with sALCL, describing overall response rate (ORR) and complete response (CR) rates of 77% and 63% respectively, median progression free survival (PFS) of 41 months (95% CI 17–62) and 5-year OS rate of 49% (95% CI 35–59) [7, 8]. The addition of etoposide to CHOP (CHOEP) has been suggested to be superior to CHOP in ALK-positive sALCL. The Nordic Lymphoma Group study [9] found a 66%

reduction in risk of death with CHOEP for ALK-positive sALCL, in multivariable cox regression ($n = 97$; HR = 0.34; $P = 0.008$). More recently, the German High-Grade non-Hodgkin's lymphoma Study Group (DSHNHL) replicated these findings in ALK-positive sALCL with a 5-year OS of 97% and a risk reduction of death of 76% with CHOEP when compared to CHOP (HR 0.24, $p = 0.002$), independent of International Prognostic Index (IPI) and age [10]. For ALK-negative sALCL, a large, single-arm phase II study by the Nordic Lymphoma Group showed an overall response rate of 82% with CHOEP-14 with 72% of patients undergoing autologous stem cell transplantation. The 5-year PFS and OS were 44% and 51% respectively [11].

More intensive approaches have also been evaluated for sALCL with no significant improvements to the historical CHOP results. A phase II trial reported hyperCVIDD/MA (cyclophosphamide, pegylated doxorubicin, vincristine, dexamethasone alternating with high-dose methotrexate/cytarabine) with a CR rate of 83% and 3-year PFS was 43% in ALK-negative patients with ALCL [12].

sALCL is characterized by 100% CD30 antigen cell surface receptor expression. The anti-CD30 antibody drug conjugate, brentuximab vedotin (BV) has transformed the treatment of relapsed sALCL following the initial high response rates seen in the phase 1 and 2 trial results leading to durable remission and survival [13, 14]. More recently, BV was investigated within first-line therapy in the ECHELON-2 trial (NCT01777152) [15], a global randomized phase 3 study of BV in combination with CHP, versus standard CHOP chemotherapy, for newly diagnosed CD30-positive peripheral T cell lymphomas (PTCL). Overall a 34% reduction in the risk of death for patients with CD30+ PTCL treated with BV-CHP and a 46% reduction in sALCL populations led to the regulatory approval of A-CHP by both the US Food and Drug Administration (FDA) (for CD30+ PTCL, in 2019) and European Medicines Agency (EMA) (for ALCL only, in 2020).

We undertook a retrospective, multicentre study of newly diagnosed consecutive patients with sALCL, treated prior to the approval of BV-CHP, in order to evaluate treatment patterns

and outcomes of sALCL in routine clinical practice, where there is a paucity of data. We also evaluated the outcomes of patients treated with single-agent BV for relapsed or refractory (r/r) ALCL in this large real-world cohort.

METHODS

Consecutively diagnosed patients with sALCL treated between October 2003 and December 2018 were retrospectively identified from institutional databases at seven haemato-oncology centres in the UK and Australia and 14 additional centres from the UK Haematological Malignancy Research Network database [16] (total patients, $n = 214$). Inclusion criteria were age at least 16 years old at diagnosis and histological confirmation of sALCL; no central pathology review was undertaken for this study but all cases had undergone expert haematopathology review and fulfilled World Health Organization (WHO) criteria for sALCL. Exclusion criteria included post-mortem diagnosis and participation in the ECHELON-2 trial. Data on DUSP22 and TP63 by fluorescence in situ hybridisation (FISH) were unavailable retrospectively.

Patient baseline characteristics, first and subsequent lines of therapy, BV use and responses in both first-line and subsequent therapy lines were recorded. Response assessment was by CT and/or PET-CT (termed PET hereafter) and assessed by local investigators using standard Deauville score and Lugano classification. Deauville scores 4–5 were considered as positive. The main outcomes of interest were time to treatment failure (TTF) and OS following first-line and BV treatment. TTF was defined as the time from the start of first-line therapy until the start of subsequent line of therapy, death or progression. Additional outcome measures included frequency of BV use for r/r ALCL and frequency of autologous stem cell transplant (ASCT) in first remission. No data on secondary malignancies was collected.

TTF and OS analyses were performed using the Kaplan–Meier method with Cox regression and the log rank test to compare groups in both univariable and multivariable analyses. The

assumption of proportional hazards was checked using the Schoenfeld residuals, and backwards selection with a p value for inclusion of 0.1 was used to select the final multivariable model. Chi-squared (or Fisher's exact) tests were used to compare frequencies between groups. All statistical analyses were performed using STATA version 15.1 (STATAcorp, Texas).

Compliance with Ethics Guidelines

All patient data were anonymised at source and treated according to the General Data Protection Regulation (GDPR) and the principles of the declaration of Helsinki. The study was a service evaluation project and exempt from ethic committee approval.

RESULTS

A total of 231 cases were initially identified, of which 17 were subsequently excluded (14 due to participation in clinical trials and three for post-mortem diagnosis). The final cohort included 214 patients, the median age at diagnosis was 52 years (range 16–93), 135 were male (63%) and 84 (40%) patients were ALK-positive. Median age for ALK-positive and ALK-negative was 35 and 61 years respectively. 35 patients (18%) had Eastern Cooperative Oncology Group (ECOG) performance status ≥ 3 . Baseline patient characteristics are summarized in Table 1 alongside the characteristics of participants of the ECHELON-2 CHOP cohort for comparative purposes.

The majority of patients received multiagent chemotherapy as first-line therapy ($N = 191$, 83%), 15 patients (7%) received palliative treatment only and 7 patients received radiotherapy (RT) only for localized stage disease. Only one patient had missing data for treatment. For those receiving chemotherapy, the median number of cycles administered was 6 (range 1–8) and median lines of therapy received was 2 (range 1–6). The most frequently employed first-line treatment regimen was CHOP in 152 patients (71%). CHOEP was given to 7 patients (3%) whereas 27 (13%) received intensified regimens (e.g. CODOX-M/IVAC,

ALCL99). The remaining five patients received other induction regimens (CVP, GCVP [two patients], IVE/methotrexate/DHAP, IVE/methotrexate). Mortality rate attributed to chemotherapy by investigators was 4% (8/191); all of these patients had received CHOP.

Amongst 198 response-evaluable patients (including those treated with RT alone $n = 7$), ORR was 71% and CR rate was 53%. When analysed by ALK status, ALK+ patients had markedly higher CR rates compared to ALK– patients (ALK+ 58% vs ALK– 37%, $p = 0.01$) with comparable ORR (ALK+ 67% vs ALK– 63%, $p = 0.59$). CHOP-treated patients had an ORR of 65% and a CR rate of 47%. The seven patients treated with CHOEP and more intensive protocols had an ORR and CR rate of 91% and 71% respectively. Twenty-three patients did not have response evaluation, mainly because of death from progressive disease ($n = 18$, counted as non-responders) and the remainder because of missing information (excluded).

A minority of patients received ASCT consolidation ($N = 20$; 9%), 10 of whom had received intensified induction regimens and nine had received CHOP. The median IPI of these patients at baseline was 2 (Table 2). The relatively low rate of ASCT was also seen in younger patients in CR1; of 30 ALK-negative patients aged less than 65 years and in CR after initial chemotherapy, only 13 (43%) underwent ASCT. Of the remaining seven patients who underwent ASCT, two were older than 65 years and five were in partial response (PR). Of note, the relapse rate in patients undergoing ASCT consolidation was 24.5% (95% CI 8.6–58.4), as compared to 22.2% (95% CI 13.7–34.7) in those potentially eligible (at least 65 years of age and in CR after induction) but who did not undergo ASCT. The International T cell Lymphoma Project recently reported similar low rates of ASCT (7%) in ALK-negative ALCL [8].

Median follow-up of was 57 months (IQR 36.3–87.2). The 4-year TTF and OS after first-line treatment were 41.5% (95% CI 34.6–48.2 months) and 58% (95% CI 50.7–64.6 months) respectively (Fig. 1). For the CHOP-treated cohort ($n = 152$), the 4-year TTF and OS were 41.2% (95% CI 33.1–49.1) and 58.9% (95% CI 50.3–66.5) (Fig. 1). ALK-negative patients'

^c For comparison

outcomes were inferior compared to ALK-positive with 4-year TTF 28.2% (95% CI 18.6–38.6) and OS of 43.9% (95% CI 32.6–54.6) vs 57.6% (95% CI 44.8–68.5) and 78.6% (95% CI 66.5–86.8), respectively (log rank $p < 0.01$) (Fig. 2). Multivariable analysis (MVA) for CHOP-treated cohort including a range of established clinical predictive factors (Table 3) showed that stage III/IV disease (HR 2.39, 95% CI 1.22–4.70, $p = 0.012$), raised LDH (HR 2.18 95% CI 1.15–4.11, $p = 0.016$) and age (10-year increase) (HR 1.29, 95% CI 1.04–1.59, $p = 0.020$) were the only factors independently associated with OS. ALK+ status was not found significant for OS (HR 0.44, 95% CI 0.18–1.07, $p = 0.071$) but retained a significant magnitude effect. ALK+ status was a significantly strong predictor of TTF (HR 0.36, 95% CI 0.21–0.63, $p < 0.001$), independently of stage, age and LDH. Additionally, B symptoms (HR 2.45, 95% CI 1.45–4.15, $p = 0.001$) and sex (HR 1.94, 95% CI 1.16–3.24, $p = 0.11$) were independently associated with TTF. Baseline demographic characteristics of the complete cases included in the MVA are shown Table 1 in the supplementary material; there were no significant differences between the groups.

Fifty-two patients received BV at relapse, mostly as second-line therapy ($N = 33$; 63%). The median number of BV cycles administered was 4 (IQR 1.5–6). The ORR to BV was 49% and the CR rate was 28%. With a median follow-up after BV was 34 months (IRQ 21.5–50.3), 3-year TTF and OS rates were 29.7% (95% CI 17.5–43.0) and 40.2% (95% CI 26.2–53.9) respectively (Fig. 1 in the supplementary material). Twelve patients were bridged to an

allogeneic SCT and seven were bridged to ASCT, 15 of these patients remained alive at data cut-off (two allo-SCT and one ASCT patient have died). When analysed by era, 80% of patients diagnosed in 2013 or beyond had received BV for r/r ALCL, as compared to only 53% of those diagnosed before 2013.

Fifty-three patients were staged with both CT and PET-CT, with 70% concordance between the two imaging modalities. Ten patients were upstaged with PET-CT, four of whom were found to have extranodal sites not identified by CT. Considering the 175 patients evaluable for treatment response, 95 had PET-CT and 61 had CT only. CR rate was 63% and 51% for PET and CT-evaluated patients, respectively. The 3-year TTF was 71.1% and 71.3% for PET and CT-defined CR respectively.

DISCUSSION

The ECHELON-2 study results have changed clinical practice for newly diagnosed sALCL. Data from our study, with mature follow-up, provides a benchmark for the performance of CHOP-like chemotherapy for sALCL treated in routine practice before the approval of BV-CHP. The demonstrated beneficial effect of the BV-CHP regimen in the trial setting is likely to be corroborated in patients with sALCL treated with the BV-CHP regimen in the real-world setting.

The survival outcomes for our cohort are comparable to data from the prospective International T cell Lymphoma Project, which described a 3-year PFS of 47% in ALK-negative

patients with ALCL [7, 8]. Comparing our findings to CHOP-treated patients in the ECHELON-2 trial, recognizing the caveat that 32% of such patients were of non-ALCL CD30+ PTCL subtypes, the outcomes of our cohort appeared inferior (3-year TTF 43.8% in our cohort vs 49% PFS in ECHELON-2). These outcomes were observed despite our CHOP-treated cohort being younger (52 years vs 58 years), with a higher proportion of ALK-positive patients (45% vs 22%) and early stage disease (stage I/II 38% vs 20%). Conversely, consistent with a real-world cohort, our study included 18% of patients with ECOG ≥ 3 (not included in ECHELON -2) which may, at least in part, explain the inferior outcomes (Table 1). ALK status remained as a strong predictor of TTF, independent of age, with ALK-positivity associated with a 64% reduction in the risk of progression. Given the known association between ALK status and age, it was of no surprise that inclusion of age in the MVA model for OS resulted in a reduction of the significance of ALK status; however, we that believe the magnitude of effect is still clinically significant as there was a 66% of reduction in risk of death for ALK-positive patients. Our results contrast with those from a French real-world cohort [10] in which an age cutoff of 40 years was associated with outcomes independently of ALK status. By treating age as a continuous variable in our model, the risk of co-segregating age and ALK status is better mitigated; hence, our results do support a strong association of ALK status with clinical outcomes. This effect was evident in our

◀**Fig. 1** TTF and OS Kaplan–Meier curves of complete cohort (a, b) and CHOP-treated cohort (c, d)

model, despite differences in median age at diagnosis between ALK+ and ALK− patients.

There are no published randomized trials comparing CHOP with other chemotherapy approaches for newly diagnosed sALCL. Retrospective studies support CHOEP in this context, the Nordic Lymphoma Group study reported improved survival outcomes (HR 0.48, 95% CI 0.32–0.74) when compared to CHOP in sALCL [9, 17]. The T cell lymphoma project also reported a trend towards improved outcomes with etoposide regimens with superior 5-year OS (56% vs 69% for etoposide-containing regimens, $p = 0.05$) and a trend towards improved 5-year PFS (39% vs 50% for etoposide-containing regimens, $p = 0.18$) [8]. However, despite the potential benefit of CHOEP in sALCL, this regimen confers increased risk of morbidity and mortality compared to CHOP, particularly for patients above 60 years of age, as reported in the German NHL-B trial [18]. In our study, there were insufficient numbers of CHOEP-treated patients to analyse this aspect in depth.

Other intensified CHOP-based regimens such as HyperCVAD [12, 19] and the CHOP-IVE-MTX regimen (extrapolating from enteropathy-associated T cell lymphoma protocols [20]) have been applied in ALCL. In our cohort, augmented CHOP regimens were associated with higher CR rates, a higher rate of ASCT consolidation (11/27 patients) and 4-year TTF of 55.7% (95% CI 33.8–72.9) and OS of 74.9% (95% CI 48.1–89.3). Outcome comparisons with CHOP were not pursued, as the baseline characteristics of these patients were non-comparable and numbers were small.

The role of ASCT for consolidation of first-line therapy in sALCL is controversial [21], although this is included as a recommendation/consideration in some guidelines [6, 22]. The ECHELON-2 study reported an ASCT rate of 22% in the CHP + BV arm compared to 17% in the CHOP arm, reflecting the improved activity of BV-CHP (higher rate of CR) [15]. It is worth

Fig. 2 TTF and OS in CHOP-treated cohort, Kaplan–Meier curves stratified by ALK status

noting that the ASCT intent in the BV-CHP arm of the ECHELON-2 trial from non-Asian countries was 49% contrasting with 32% who actually underwent ASCT [23]. There are no randomized studies evaluating ASCT in first response for PTCL or sALCL. A recent multinational retrospective study found no survival advantage of ASCT consolidation as first-line therapy in PTCL [24] with a reported rate of ASCT consolidation of 46% for sALCL. Conversely, a recent US retrospective real-world study revealed an ASCT rate of only 10%, which is consistent with our cohort, where only 9% underwent ASCT consolidation [19]. Interestingly, ALK-negative patients with ALCL who underwent ASCT had comparable relapse rates

to those in CR who did not. This observation has been replicated by a number of other retrospective studies, with an overall lack of clear benefit of ASCT in first remission [9, 11, 19, 25–27].

As for response evaluation, some studies have established a clear predictive value of response by PET in T cell lymphoma. A retrospective Japanese study ($N = 36$) showed that 3-year PFS rates in the positive and negative PET patients post induction were 18% and 62% respectively [28]. A larger study including 124 patients showed independent OS benefit of PET response with a HR of 3.3 (95% CI 1.32–8.56) for patients with Deauville > 3 at end of treatment [29]. Our results suggest that demonstrating CR by either PET or CT is associated with higher rates of TTF at 3 years, underlining the positive impact of chemosensitive disease in the outcomes of sALCL.

CONCLUSIONS

Our study provides descriptive outcomes of one of the largest multicentre population of sALCL available, confirming ALK-status as a strong and independent predictor of TTF and with non-significant but clinically relevant effect on OS. We highlight a low uptake of ASCT consolidation after frontline ALCL therapy, despite being frequently recommended within guidelines and expert recommendations. Our findings likely reflect the uncertainty of evidence supporting this approach. We also highlight the presence of a minority of patients who received BSC from the outset, representing a group with unmet need, for whom novel, low-toxicity and efficacious agents are needed. The present results highlight some degree of patient selection in the pivotal BV trials in the relapsed and frontline setting and serve as an appropriate benchmark for the comparison of patient outcomes treated with frontline BV-CHP. Further research to gather real-world evidence of BV-CHP combination will be desirable.
