Abstract

1. The use of functional diversity analyses in ecology has grown exponentially over the past two decades, broadening our understanding of biological diversity and its change across space and time. Virtually all ecological sub-disciplines recognise the critical value of looking at species and communities from a functional perspective, and this has led to a proliferation of methods for estimating contrasting dimensions of functional diversity.
2. Differences between these methods and their development generated terminological inconsistencies and confusion about the selection of the most appropriate approach for addressing any particular ecological question, hampering the potential for comparative studies, simulation exercises and meta-analyses.
3. Two general mathematical frameworks for estimating functional diversity are prevailing: those based on dissimilarity matrices (e.g. Rao entropy, functional dendrograms) and those relying on multidimensional spaces, constructed as either convex hulls or probabilistic hypervolumes.
4. We review these frameworks, discuss their strengths and weaknesses and provide an overview of the main R packages performing these calculations. In parallel, we propose a way for organising functional diversity metrics in a unified scheme to quantify the richness, divergence and regularity of species or individuals under each framework. This overview offers a roadmap for confidently approaching functional diversity analyses both theoretically and practically.

KEYWORDS

alpha diversity, beta diversity, biological trait, functional dendrogram, functional dispersion, functional regularity, functional richness, hypervolume

1 | INTRODUCTION

The idea that organisms are not equal in their attributes and functions—that is, the range of things they do (Petchey & Gaston, 2006)—is old. For example, as early as the fourth century BC Theophrastus recognised that plants can be classified into groups sharing similar characteristics (traits) such as woodiness and size.

Similar pioneer observations found a more formal definition with the introduction of the concept of the ecological niche (Elton, 1927; Grinnell, 1917; Hutchinson, 1957) and the subsequent emergence of functional ecology as a scientific discipline (Calow, 1987). When the homonymous journal *Functional Ecology* was launched in 1987, its Editorial Board was cautious, perhaps even skeptical, about the potential success of this discipline. They wrote: '*Your immediate reaction*

to this first issue [...] might be to throw up your arms in despair at the thought of yet another primary, scientific journal' (Editorial, 1987). It made us smile to read at this editorial with hindsight, now that functional information proved to be a key pillar of modern ecology (de Bello, Carmona, et al., 2021; Malaterre et al., 2019) and an important dimension of biodiversity (Jarzyna & Jetz, 2016).

Over the past two decades, we have witnessed an exponential growth of trait-based studies. This was primarily driven by a number of seminal essays that illustrated a way of rethinking entire ecological fields from a functional perspective, from population and community ecology (McGill et al., 2006; Violle et al., 2012) to biogeography (Violle et al., 2014), along with conservation biology (Cadotte et al., 2011; Rosenfeld, 2002; Wellnitz & Poff, 2001). Stemming from this intellectual legacy, the use of functional diversity in the study of ecological patterns across different spatial and temporal scales has now become routine (Jarzyna & Jetz, 2018; Kraft & Ackerly, 2010; Lamanna et al., 2014; Mason & De Bello, 2013; Safi et al., 2011).

This fast theoretical development was accompanied by a proliferation of methods for studying functional diversity (de Bello, Carmona, et al., 2021; Legras et al., 2018). There is nowadays a wide variety of algorithms and frameworks (hereafter 'methods') that can be used to delineate the trait space occupied by a given species or community, each based on particular mathematical objects—raw data, distance matrices, trees, convex hulls, kernel density hypervolumes, etc. (see Table 1 for a glossary). Once the trait space is generated, an even larger set of indices (hereafter 'metrics') is available to calculate specific properties of the system (Pavoine & Bonsall, 2011; Schleuter et al., 2010). Albeit this broad availability of methods and metrics is fuelling gigantic leaps forward in our understanding of ecosystem functionality, it has been pointed out that it is also [...] causing much confusion in selecting appropriate methods for specific questions' (Carmona et al., 2016b).

In our view, this confusion is the direct consequence of two drivers. First, there have been few efforts to compare each method to illustrate their strengths, weaknesses and limitations. Our experiences as reviewers and editors of manuscripts, readers of the existing literature and instructors of early career scientists have led us to think that most users routinely use a single method or metric just because it has been published in a famous paper or it appears in the first page of Google, and not because it better fits their question and data. Second, researchers developing the statistics underlying functional diversity approaches often provided the user with a limited selection of functions for calculating functional metrics or used different denominations to metrics with similar properties.

In the last decade or so, there have been subsequent attempts to categorise functional metrics and explore their usefulness in discriminating different processes (e.g. Mason et al., 2005; Mouchet et al., 2010; Ricotta, 2007; Villéger et al., 2008). Building upon this ground, Pavoine and Bonsall (2011) provided a broad clarification of the mathematics underpinning this plethora of metrics, categorising them under three independent dimensions of richness, divergence and regularity (Box 1). The Pavoine–Bonsall scheme is compelling, allowing the grouping of taxonomic, phylogenetic and functional

BOX 1 The Pavoine–Bonsall scheme for classifying taxonomic, phylogenetic and functional metrics

Pavoine and Bonsall (2011) proposed a semantic taxonomy for classifying taxonomic, phylogenetic and functional metrics under a unified scheme. This classification was further improved by Tucker et al. (2017), who identified three distinct dimensions of diversity: *richness*, *divergence* and *regularity*. These three dimensions capture the primary mathematical operation inherent in each metric, namely:

1. The 'richness' dimension encompasses metrics reflecting the sum of differences among observations;
2. The 'divergence' dimension encompasses metrics reflecting the average differences among observations; and
3. The 'regularity' dimension encompasses metrics reflecting how regular the differences among observations are.

This scheme is general as it can be applied to both abundance, presence/absence or other data, and provides a simple and intuitive rationale for grouping functional metrics. The classification scheme is also split on a second axis of information, reflecting the level of data organisation at which each metric is calculated (*Group*). In their classification of phylogenetic indices, Tucker et al. used two levels of organisation, depending whether each metric is calculated within a set (e.g. individuals within a species or species within a community; so-called α -diversity) or between sets (e.g. comparison of multiple species or communities in space and time; so-called β -diversity). Here, we expanded this second axis of information to three levels of organisation, namely:

1. 'Observation level', representing the distinct functional elements within a set (e.g. an individual, population or species);
2. 'Within groups', representing all the *Observation level* elements within a set (e.g. functional diversity within a population, species, community or region); and
3. 'Between groups', comparing multiple *Groups* (e.g. comparison of multiple populations, species, communities or regions in space and time).

metrics under a common umbrella that well encapsulates a modern view on biodiversity (Jarzyna & Jetz, 2016). Yet, the classification still presents limitations (e.g. it does not account for a beta-diversity level; Box 1) and was not fully incorporated in the available statistical packages for functional diversity calculation, which often provide the user with an incoherent set of metrics to explore these three dimensions.

Altogether, these shortcomings generate a fertile ground for terminological and conceptual confusion, which leads to a parallel

TABLE 1 Glossary of terms. Modified from Guillerme et al. (2020)

Term	Mathematics	Definition	Examples in literature
<i>Trait matrix</i>	Matrix ($n \times d$)	The matrix reporting the traits of the studied system. It reflects the variation of traits in the <i>trait space</i> occupied by a certain ecological or evolutionary unit	Functional space, ecospace, dissimilarity matrix, etc
<i>Observations</i>	Rows (n)	The units of focus in the study	Taxa, individuals, populations, morphospecies, species, etc
<i>Traits</i>	Columns (d)	The number of elements (traits) that were measured for each <i>Observation</i> or any transformation thereof (e.g. principal components)	Traits, ordination scores, distances, principal components, etc
<i>Observation matrix</i>	Matrix ($m \times n$)	Optional matrix that provides attributes for the <i>Observations</i> (e.g. abundances, weights) and the subdivision of the <i>Trait matrix</i> into relevant <i>Groups</i>	Abundance data, community data, incidence data, biomass data, etc
<i>Groups</i>	Rows (m)	The meaningful groups of observations for answering the research question(s) of interest	Communities, ecosystems, species, clades, geological strata, etc
<i>Trait space</i>	Graphical representation of the <i>trait matrix</i> .	Any transformation and/or visualisation (graphic representation; usually a 2D or 3D projection) of the <i>trait matrix</i> . It represents the space in which <i>functional metrics</i> are most often visualised	Hypervolume, convex hull, functional dendrogram, probability density, etc
<i>Functional metric</i>	Statistic (i.e. a measure)	The metric is the aspect(s) of interest that attempts to summarise some intrinsic feature of the variation in the <i>trait space</i> . This is what is measured (usually at the level of the <i>group</i>) to answer the research question(s) of interest	Richness, divergence, regularity, functional index, functional diversity, functional richness, beta functional diversity, trait dispersion, trait divergence, etc

confusion about the selection of the most appropriate methods and metrics for addressing any particular ecological question. This hampers the potential for comparative studies and meta-analyses, meanwhile preventing a full understanding of the eco-evolutionary rationale beyond functional diversity estimation. We aim, therefore, to propose a classification of the existing jungle of functional methods, dimensions and metrics. To achieve this goal, we first review the main frameworks and R packages for estimating functional diversity that are emerging in trait-based ecology. We explain the ecological logic underpinning each framework (i.e. how each method relates to the concept of niche) and discuss their pros and cons. We then illustrate the meaning of the three dimensions of functional diversity—richness, divergence and regularity (Box 1)—in the context of each of these methods. Finally, we present the metrics quantifying each dimension within each method and which R packages calculate them. Our ultimate goal is to develop a roadmap to select the best possible functional diversity approach depending on the question under study.

2 | MATHEMATICAL METHODS FOR FUNCTIONAL DIVERSITY ESTIMATION

Stemming from the concept of the ecological guild, the simplest mathematical estimation of functional diversity can be achieved using a raw data matrix of traits, whereby total functional richness is calculated as the number of unique functional combinations (guilds) in a given set of observations (Blondel, 2003). Although the idea of guild provides an intuitive representation of functional diversity,

researchers soon felt that this approach was too simplistic (Legras et al., 2018). A plethora of more sophisticated methods has since been developed to represent the observed diversity of traits in a system and their relations. We will refer to this representation of the diversity of traits as the ‘trait space’ throughout this review (Table 1).

Rather than overviewing all published and used methods, which would probably create further confusion, we seek to illustrate a way to frame the plethora of possibilities for trait space analyses. We chose to only discuss methods that:

1. Are open and free, which today practically coincide with packages and functions implemented and maintained in R (Lai et al., 2019);
2. Are accessible to the largest possible audience, namely methods that are thoroughly documented and thereby do not require a high level of knowledge in mathematics, statistics or programming; and
3. Are based on robust mathematical concepts that provide an easy-to-understand representation of the trait space.

In our view, two general mathematical approaches for estimating the trait space and its properties are prevailing in recent literature: those based on non-ordinated matrices (non-dimensional representation) and those based on ordinated multidimensional spaces (i.e. multidimensional representation). We hereafter briefly describe each of these methods, discuss their strengths and weaknesses (Table 2), and list the main R packages (Table 2) and functions (Table 3) that can be used for practical calculations.

TABLE 2 Advantages and disadvantages of the existing frameworks for functional diversity. Main R packages for calculation are given in alphabetic order

Family	Method	Advantages	Disadvantages	R packages
Raw data	Functional guild or any other raw representation of the traits	Simplest approach Rooted in a milestone ecological concept: the guild Easily communicated or visualised, even for the general public	Functional guild transforms continuous traits into categories, with consequent loss of information Does not provide a direct link with the niche concept The selection of the relevant number of groups is often subjective The delimitation of groups is subjective	stats
Dissimilarity-based methods	Mean dissimilarity methods	Allow considering abundances Clear biological interpretation. (average dissimilarity between the individuals composing a group) Clear correspondence with variance, which allows using an analysis of variance framework (De Bello et al., 2011) Allow for partitioning of diversity across scales (de Bello et al., 2010; Pavoine et al., 2016) Can be applied to other aspects of diversity (taxonomic, phylogenetic) using a single coherent mathematical framework (Chao et al., 2014; Pavoine et al., 2016)	There is not a single entropy-based framework to measure richness, divergence and regularity components of the trait matrix Does not come with a clear graphical representation of the trait space—although possibilities do exist (Bruehlheide et al., 2018; Carmona et al., 2012) Choice of distance measure is not trivial; should be considered carefully as it may affect results significantly (De Bello et al., 2013) Not intuitively linked to the concept of species niche Diversity does not necessarily increase when more observations or traits are added (this may also be seen as an advantage, e.g. when calculating redundancy)	ade4 (Dray & Dufour, 2007); adiv ^a (Pavoine, 2020); BAT ^a (Cardoso et al., 2015, 2021); entropart (Marcon & Hérault, 2015); FD ^a (Laliberté et al., 2014); funrar ^a (Grenié et al., 2017); hillR ^a (Li, 2018); picante (Kembel et al., 2010); TPD ^a (Carmona, 2019)
	Functional dendrogram (= functional tree)	Intuitive visual presentation, potentially allows the calculation of all functional diversity metrics by hand (easy error checking) The theoretical understanding of tree objects properties is vast, thanks to a long tradition of phylogenetic studies Can be applied to other aspects of diversity (taxonomic, phylogenetic) using a single coherent mathematical framework based on trees (Cardoso et al., 2015)	Not sensitive to abundances when calculating richness Choice of distance measure for tree estimation is not trivial; should be considered carefully as it may affect results significantly (Podani & Schmera, 2006) Not intuitively linked to the concept of ecological niche	adiv ^a ; BAT ^a ; vegan (Oksanen et al., 2018)
Multidimensional space	Binary hypervolume (= convex hull)	Intuitive visual presentation of the trait space (Cornwell et al., 2006) Conceptually simpler than probabilistic hypervolumes Computationally faster than probabilistic hypervolumes	Only suitable for exploring the Richness dimension of functional diversity (see Table 3) Curse of dimensionality (Bellman, 1957): a linear increase in the number of dimensions requires an exponential increase in the number of observations. Also, computation time scales exponentially with the number of dimensions (Blonder, 2016; Guillerme et al., 2020; Mammola, 2019) Do not allow the existence of variable densities in the trait space—'convex hull expectation' (Blonder, 2016) Extremely sensitive to outliers: a single functionally distinct observation may significantly affect the estimation of the volume Performs poorly with low sample size Cannot consider abundances when calculating richness Categorical traits are not fully implemented in the calculation—although possibilities do exist (e.g. Carvalho & Cardoso, 2020; Lloyd, 2016, 2018)	BAT ^a ; betapart (Baselga et al., 2018); FD ^a

(Continues)

TABLE 2 (Continued)

Family	Method	Advantages	Disadvantages	R packages
	Probabilistic hypervolume	Stems from a milestone theoretical concept in ecology: the Hutchinsonian niche (Hutchinson, 1957) Allow considering abundances A density-based description of the trait space enhances the possibility to explore areas of higher and lower functional density within the boundaries of the hypervolume (Blonder, 2016; Carmona et al., 2019)	Curse of dimensionality (see above) Categorical traits are yet not fully implemented—although possibilities do exist (see above) For stochastic hypervolumes, might require performing iterations and reporting results using null modelling techniques Sensitive to the choice of bandwidth when kernel density estimations are used Diversity does not necessarily increase when more observations or traits are added [negative contribution sensu Mammola and Cardoso (2020); this may also be seen as an advantage, e.g. when calculating redundancy] Time consuming for big or complex datasets	BAT ^a , dYNRB (Junker et al., 2016), hypervolume (Blonder, 2018), nicheROVER (Swanson et al., 2015), TPD ^a

^aPackages with a large set of complementary functional metrics to explore the richness, divergence and regularity components of the trait space.

2.1 | Methods based on non-dimensional representation

All these methods rely on converting the trait matrix to a dissimilarity matrix; in turn, this transformed matrix serves to delineate the trait space and explore its properties. Here, we distinguished between methods and metrics that attempt to measure the entropy of the trait space as the dissimilarity among observations directly and those that use a distance-based dendrogram object to represent the trait space.

Whereas all these methods have several features that may make them advantageous over multidimensional frameworks, there are at least two main caveats that apply to all. Foremost, they do not relate well with the classical concept of niche sensu Hutchinson (1957) in that they do not organise the trait space according to defined niche axes. Second, the choice of the distance measure to use is not trivial, especially because a trait matrix is frequently a mixture of different datatypes—continuous, ordinal, categorical and binary data—and this can significantly affect results (Podani & Schmera, 2006).

2.1.1 | Mean dissimilarity methods

The methods in this category are based on the notion that functional diversity represents the extent of trait differences between species (de Bello et al., 2016; Scheiner et al., 2017). These methods do not allow the visualisation of the trait space directly [but see, e.g. Micó et al. (2020) for a workaround], and are more a collection of metrics measuring entropy-based properties of the trait matrix. Four commonly used metrics are:

1. Rao quadratic entropy (Rao), representing the expected dissimilarity between two different individuals, populations or species sampled at random (Botta-Dukát, 2005);
2. Functional dispersion (FDIs) sensu Laliberté and Legendre (2010), representing the weighted mean distance of individual species to the centroid of all species;
3. Mean pairwise dissimilarity (MPD), representing the expected dissimilarity between two randomly selected species without replacement (Weiher & Keddy, 1995); and
4. Hill numbers, representing the effective number of equally abundant and functionally distinct species within a group (Chiu & Chao, 2014).

The differences between these metrics are subtle, but with important practical consequences. Both Rao and FDis have the same mathematical basis as variance (Pavoine & Bonsall, 2011) so that they are considered to be fundamentally equivalent (de Bello, Carmona, et al., 2021). Conversely, in MPD the expected dissimilarity is estimated only considering individuals from different species, thus it does not allow to account for intraspecific variability, unlike Rao. The great advantage of using mean dissimilarity methods versus others is their clear link with taxonomic and phylogenetic diversity (Chao

TABLE 3 A 'periodic table' organising functional diversity metrics. The classification is adapted from the Pavoine–Bonsall scheme (Box 1). The row entries distinguish between observation, within groups, and between groups levels; column entries represent the three dimensions of richness, divergence and regularity under the main frameworks identified in this study. The table is expanded from that proposed in Mammola and Cardoso (2020). Examples of R functions for calculation (ordered alphabetically) are mostly taken from packages fully devoted for functional diversity estimations (see Table 2)

Dimension		RICHNESS (... how much?)					DIVERGENCE (... how different?)	
Framework:		Raw data	Mean dissimilarity	Functional dendrogram	Binary hypervolume	Probabilistic hypervolume	Raw data	Mean dissimilarity
OBSERVATION LEVEL	Metric:	Contribution to richness					Originality / Uniqueness	
	Question:	How much does an observation add to the total trait space?					How different is an observation to the others?	
	Example calculation:	For each observation is 1 divided by the number of observations with the same combination of traits	-	Edge length provided by an observation	Contribution of an observation to the total volume of a convex hull	Contribution of an observation to the total volume of a probabilistic hypervolume (can be negative)	The distance of each functional observation from the average of the trait itself.	Average distance between an observation and all others (originality) or between an observation and the closest (uniqueness)
	Example R function(s):	n.a.	n.a.	BAT::contribution; vegan::spantree	BAT::hull.contribution	BAT::kernel.contribution	n.a.	funrar::uniqueness
WITHIN GROUPS	Metric:	Richness					Divergence	
	Question:	What is the size of the trait space?					How dispersed is the trait space?	
	Example calculation:	Number of unique combinations of traits (or weighted mean of the trait values)	Number of equivalent observations (i.e. maximally dissimilar observations needed to produce the observed diversity). Or, the effective total distance between observations in the group	Total branch length of the functional tree	Volume of the convex hull or sum of areas of successive convex hulls (after Fontana et al., 2016)	Volume of the hypervolumes or, in TPD, the sum of cells where trait probability density >0 (Carmona et al., 2016a, 2016b)	Standard deviation of functional observations	Expected dissimilarity between two observations randomly taken from the group (De Bello et al., 2011) or average distance of observations to a centre of the trait space (Laliberté & Legendre, 2010)
	Example R function(s):	BAT::cwm; FD::sing.sp; FD::functcomp	div::EqRao; hillR::hill_func; TPD::Rao	BAT::alpha	BAT::hull.alpha; FD::dbFD	BAT::kernel.alpha; TPD::REND	BAT::cwd	FD::Fdis; TPD::Rao
BETWEEN GROUPS	Metric:	Beta richness					Beta replacement	
	Question:	How dissimilar is the size of multiple trait spaces?					How distant are multiple trait spaces?	
	Example calculation:	Net difference in the number of distinct functional observations	Number of equivalent observations estimated at nested scales Or the effective number of equally large and completely distinct group pairs	Net difference in summed length of edges of functional dendrograms (beta richness sensu Cardoso et al., 2014)	Net difference in amplitude of binary hypervolumes (or nestedness sensu Villéger et al., 2013)	Net difference in amplitude of probabilistic hypervolumes (Carvalho & Cardoso, 2020)	Replacement of distinct functional observations between groups	Divergence among different groups.
	Example R function(s):	n.a.	adiv::EqRao; hillR::hill_func_parti; TPD::Rao	BAT::beta	BAT::hull.beta; betapart::functional.beta.multi	BAT::kernel.beta	n.a.	ade4::disc; TPD::Rao

Abbreviation: n.a., No specific function available.

REGULARITY (... how regularly?)							
Functional dendrogram	Binary hypervolume	Probabilistic hypervolume	Raw data	Mean dissimilarity	Functional dendrogram	Binary hypervolume	Probabilistic hypervolume
Contribution to evenness							
How much does an observation increase the regularity?							
Average distance between an observation and all others (originality) or between an observation and the closest (uniqueness) in the tree	Not applicable: a convex hull, being homogeneous, is equally dispersed throughout	Average distance between an observation and a sample of random points within the probabilistic hypervolume, or overlap between the TPD function of a single observation and the TPD function of the whole set of observations	Contribution of an observation to the evenness of a community	Contribution of an observation to the evenness of a community	Contribution of each observation to the evenness of the functional dendrogram	Not applicable: a convex hull, being homogeneous, is even throughout	Contribution of an observation to the evenness of a probabilistic hypervolume
BAT::originality; BAT::uniqueness	n.a.	BAT::kernel.originality; TPD::uniqueness	n.a.	n.a.	BAT::evenness.contribution	n.a.	BAT::kernel.evenness.contribution
Evenness							
How regular is the trait space?							
Average dissimilarity between any two observations in the tree	Not applicable: a convex hull, being homogeneous, is equally dispersed. One can, however, potentially approximate it as the perimeter divided by area	Average dissimilarity between any two random points within the boundaries of the hypervolume or the distance between random points and the centroid	Regularity of trait values, reflecting trait abundances and distances between values Approximated as the kurtosis of traits (Gross et al., 2017) or weighted evenness of the traits	Regularity of abundances and distances along the minimum spanning tree linking all observations (Villéger et al., 2008); or deviation in the uniqueness	Regularity of abundances and distances between observations in the tree	Not applicable: a convex hull, being homogeneous, is even throughout	Overlap between the hypervolume and an imaginary hypervolume where traits are evenly distributed within their possible range (Carmona et al., 2019; Mammola & Cardoso, 2020)
BAT::dispersion	n.a.	BAT::kernel.dispersion; TPD::REND	BAT::cwe	FD::feve; funrar::uniqueness	BAT::evenness	n.a.	BAT::kernel.evenness; TPD::REND
Beta evenness							
How different is the regularity of multiple trait spaces?							
Replacement of the edges of functional dendrograms (beta replacement sensu Cardoso et al., 2014)	Replacement of functional space enclosed by convex hulls (or turnover sensu Villéger et al., 2013)	Replacement of functional space enclosed by probabilistic hypervolumes (Carvalho & Cardoso, 2020) or overlap between probability density function	Difference in evenness values between two groups	Difference in evenness values between two groups	Difference in evenness values between two functional dendrograms.	Not applicable: a convex hull, being homogeneous, is even throughout	Difference in evenness values between two probabilistic hypervolumes
BAT::beta	BAT::hull.beta; betapart::functional.beta.multi;	BAT::kernel.beta; BAT::kernel.similarity; TPD::dissim;	n.a.	n.a.	BAT::beta.evenness	n.a.	BAT::kernel.beta.evenness

et al., 2014; De Bello et al., 2010; Hevia et al., 2016). Another advantage is that all these metrics allow the incorporation of information on species abundances on estimations of functional diversity, as well as using trait data containing missing information (as long as the dissimilarity index chosen allows for it).

Yet, they present disadvantages as well (Table 2). Besides the general caveats discussed before, probably the main limit is that there is no single mean dissimilarity metric able to measure the richness, divergence and regularity components of the trait space. While Rao and related metrics are well suited to estimate the divergence component, they do not serve well in other research scenarios. Also, a consequence of the mathematical relationship between Rao (and, as a corollary, of FDis) and Simpson's index is that Rao is not independent of species richness, but rather has an asymptotically increasing relationship with it (Carmona, Guerrero, et al., 2017).

2.1.2 | Functional dendrograms

In a milestone paper, Petchey and Gaston (2002) proposed to represent the trait space of a given community or site as the dendrogram of the functional relationships (distances) among species, whereby total functional richness can be calculated as the total branch length of the tree. A dendrogram representation of the trait space is graphically intuitive, allowing the visualisation of functional relations among species or individuals. Moreover, this way of calculating the trait space is strongly linked with tree-based phylogenetic diversity (Faith, 1992), thereby offering a congruent framework based on tree objects for comparing different dimensions of biodiversity (phylogenetic and functional diversity). A dendrogram-based representation of the trait space presents, of course, disadvantages as well (Table 2). Beside the one previously discussed about the lack of direct relationship with species niches, dendrograms might change the between-species dissimilarities compared with the dissimilarity matrix initially used to build them (Maire et al., 2015; Mouchet et al., 2008).

2.2 | Methods based on multidimensional spaces

Making the closest analogy with the Hutchinsonian niche, Rosenfeld (2002) defined functional diversity as the distribution of observations in a multidimensional space whose axes represent the traits of interest. In other words, the position of observations in a multidimensional space can be used to characterise different aspects of a multidimensional object (hypervolume) encompassing all trait values observed in the group.

The interest in multidimensional representations of the trait space (and of the ecological niche; Holt, 2009) is growing. For example, it has been ironically pointed out that there are now probably *'as many definitions of these multidimensional spaces [...] as there are questions that can be tackled with such methods'* (Guillerme, 2018). Here, in a way of synthesis, we grouped methods into two families:

those that achieve a binary description of the trait space depending on whether it is occupied or not, and those that achieve a probabilistic description of the trait space by modelling the density of observations.

2.2.1 | Binary hypervolumes

A convex hull—the smallest convex polyhedron surrounding a set of observations—is arguably the simplest type of hypervolume and provides an intuitive geometrical representation of the trait space that easily embodies the often continuous nature of species' traits (Cornwell et al., 2006). This approach was first introduced by Cornwell et al. (2006) and later popularised by Villéger et al. (2008) who described a way to use convex hulls for functional richness estimation and to explore turnover among communities (Villéger et al., 2013). Convex hulls have a long tradition of use in functional ecology, and their performance has been tested across most kingdoms of life, biomes and spatial scales (Mouillot et al., 2021). A convex hull is advantageous over rectangular representation of the trait space because it excludes the 'missing corners' of irregular distributions. In $n \geq 2$ dimensions, it also reduces the amount of empty space compared to (hyper-)cubes or (hyper-)spheres (Cornwell et al., 2006). Finally, convex hulls potentially have faster computation times than probabilistic hypervolumes.

Yet, convex hulls have two main shortcomings in functional ecology (Table 2). First, they are very sensitive to outliers. Second, they can only be used to explore the richness dimension of functional diversity (Table 3). Furthermore, the space within extreme values of a convex hull is assumed to be homogeneous, implying that the trait space is uniformly occupied within extreme trait values (Blonder, 2016; Mammola & Cardoso, 2020). This can be seen as either a limitation or a feature of this type of trait space representation, emphasising the intrinsic difference between convex hulls and probabilistic hypervolumes. To partly remedy this problem, Gruson (2020) recently proposed a way for creating 'concave' hulls (i.e. including voids or pockets) based on α -shapes. Whereas the approach was developed to estimate the colour volume of organisms, it could be easily generalised to other traits.

2.2.2 | Probabilistic hypervolumes

Rather than assuming that the trait space is homogeneous, as in a convex hull, density-based approaches allow the detection of areas of higher or lower density in the multidimensional space (Blonder, 2016). Thus, probabilistic hypervolumes reflect the notion that not all areas within the boundaries of a given trait space are filled with the same intensity. This representation of the trait space better reflects the concept of niche by Hutchinson (1957), who envisioned that a multidimensional niche should have internal differences in 'density'—although, at the time, there were no methods for similar computations.

The popularity of probabilistic hypervolumes is steadily increasing in functional ecology, as testified by the number of R algorithms published in recent years allowing to delineate and/or analyse probabilistic hypervolumes (Blonder et al., 2014; Blonder et al., 2018; Brown et al., 2020; Carmona et al., 2019; Carvalho & Cardoso, 2020; Junker et al., 2016; Lu et al., 2020; Mammola & Cardoso, 2020; Swanson et al., 2015). Inevitably, these representations of the trait space, like any other, also present shortcomings, at least in their present formulation (Table 2). The plot density will depend on the method and parameters used, and there are no clear guidelines on the best options (Mammola, 2019). Also, these methods are computationally demanding, especially in high dimensions (Mammola & Cardoso, 2020).

3 | DIMENSIONS OF FUNCTIONAL DIVERSITY FOR SPECIFIC RESEARCH QUESTIONS

Most often than not, the reason for characterising a trait space is to explore its properties in relation to a research question of interest (Figure 1; Appendix S1). This can be achieved by interrogating the trait space at a specific level of organisation under the domain of richness, divergence and regularity. Here we propose a way to group existing functional metrics using a simple, unifying scheme (Table 3). This is an attempt towards providing some order to the avalanche of available metrics, useful for applying the richness, divergence and regularity notions (Box 1) to different levels of organisation and spatial scales. Interestingly, besides emphasising how there is both complementarity and redundancy in the metrics for exploring the trait space, this exercise of classification allowed us to point to the existence of gaps in what is currently available, potentially stimulating future developments of new metrics.

3.1 | Level of organisation

Existing metrics can be divided according to the level of data organisation at which they are calculated. Metrics can be calculated for individual observations (individuals, populations or species), within groups (e.g. individuals within a species or species within a community; so-called α -diversity), or between groups (e.g. comparison of multiple species or communities in space and time; so-called β -diversity).

3.1.1 | Observations

Observations contribute differently to the trait space occupied by a population, species or community, or to the differences between populations, species or communities. Different measures have been developed to reflect the position of an observation in the trait space relative to other observations, including originality, uniqueness and

contribution (Table 3). All these measures quantify in different ways how dissimilar an observation is from all others and hence how much it adds to the group measures. This can be applied to the richness, divergence or regularity, allowing the mapping of the different components of functional rarity and commonness (Grenié et al., 2017; Kosman et al., 2019; Violle et al., 2017) at different scales of organisation (Carmona, de Bello, et al., 2017).

3.1.2 | Within groups

The within-group level, often referred to as alpha diversity or simply α , reflects the properties of a group of observations without reference to other groups. Observations add to the occupation of a given trait space that characterises in different ways a species or community. This is by far the most explored level in functional diversity studies.

3.1.3 | Between groups

Differences between groups reflect the natural heterogeneity in nature, whereby populations, species and communities differ in space and time. Also called beta diversity or β , this property was first defined as the extent of change in community composition along gradients (Whittaker, 1960). Since then, the term has expanded its use, although always encompassing some kind of compositional heterogeneity or differentiation (Anderson et al., 2011; Tuomisto, 2010a, 2010b). Importantly, two distinct processes shape species or communities and their functional differences: substitution of trait space and net gain or loss of trait space [see Carvalho and Cardoso (2020) for species and Cardoso et al. (2014) for communities]. When comparing groups, one may understand how niche shifting in space or time relates to competition or ecological release and consequent evolution of traits (Carvalho & Cardoso, 2020), or to explore how trait diversity decays with spatial distance or change through time (Pavoine & Bonsall, 2011).

3.2 | Measured property

Once the level(s) of organisation of interest has been identified, one can explore the trait space by measuring its properties in the domain of richness, divergence and regularity (Box 1). Examples of specific research scenarios and questions in functional diversity are provided in Appendix S1.

3.2.1 | Richness

When estimating functional richness, one tries to answer questions related to the amount of trait space occupied by assemblages as well as how it varies in space and time. These include questions such

FIGURE 1 A general workflow for functional diversity analyses. The scheme is structured as a decision tree to guide the researcher throughout a hypothetical analysis. The Input data & data exploration phase pertains to the assemblage of the observation (incidence, abundance, biomass, etc.) and trait matrices—the raw material for any functional diversity analysis. Once the data have been cleaned and inspected, one can move on and delineate and explore the trait space using one of the many approaches discussed in this review (Table 2). Then, the most appropriate metrics (Table 3) to characterise the properties of the trait space of interest depend on the research question of interest (Appendix S1)

as what ecological processes and ecosystem services we lose if a species goes extinct or a community change (Cadotte et al., 2011; Cooke et al., 2019), the filtering effect of a given habitat on species traits (Martínez et al., 2021; Micó et al., 2020), and how does the functionality of a community vary through seasons (Rocha et al., 2012). At a broader, macroecological scale, many studies have explored variations in functional richness along gradients of thermal seasonality (latitude; Graco-Roza et al., 2021; Lamanna et al., 2014; Schumm et al., 2019), glacier cover (Brown et al., 2018) or urbanisation (Buchholz et al., 2020; Sol et al., 2020). Mapping the richness of traits can also serve to identify areas of conservation priority based on criteria beyond species richness (Brum et al., 2017; Strecker et al., 2011). For example, one can estimate the importance of both common and rare species to the net ecosystem functionality (Chapman et al., 2018), define species-level conservation priorities (Davic, 2003; Kosman et al., 2019) and even compare extinction risk across different taxa (Carmona et al., 2021).

3.2.2 | Divergence

Metrics classified under the divergence component of functional diversity seek to assess differences among observations (Gregorius & Kosman, 2017), namely the extent to which they spread across the occupied trait space (Anderson, 2006), usually relative to a mean or centroid (Mason et al., 2005; Villéger et al., 2008). A high dispersion is often interpreted as reflecting a high degree of competition between species with similar traits, and/or relaxed ecological filters (Perronne et al., 2017). Some authors also interpreted dispersion as a measure of functional redundancy (Galland et al., 2020), whereby, theoretically, less redundant communities should be those characterised by less stringent ecological filters (Ricotta et al., 2020). From the perspective of biological conservation, more functionally redundant systems should show greater resilience to perturbation (Mouillot et al., 2014), for example, when facing the extinction or disappearance of a single species, the roles performed by it can be done by functionally close species.

3.2.3 | Regularity

The regularity component, or evenness, reflects the regularity of observations' distribution within the trait space (Mouillot et al., 2005; Schleuter et al., 2010). In terms of raw data, regularity often measures the skewness of trait values; graphically, it can be seen as a measure of how harmonious the shape of the occupied trait space is—the symmetry of branches in a functional dendrogram or the

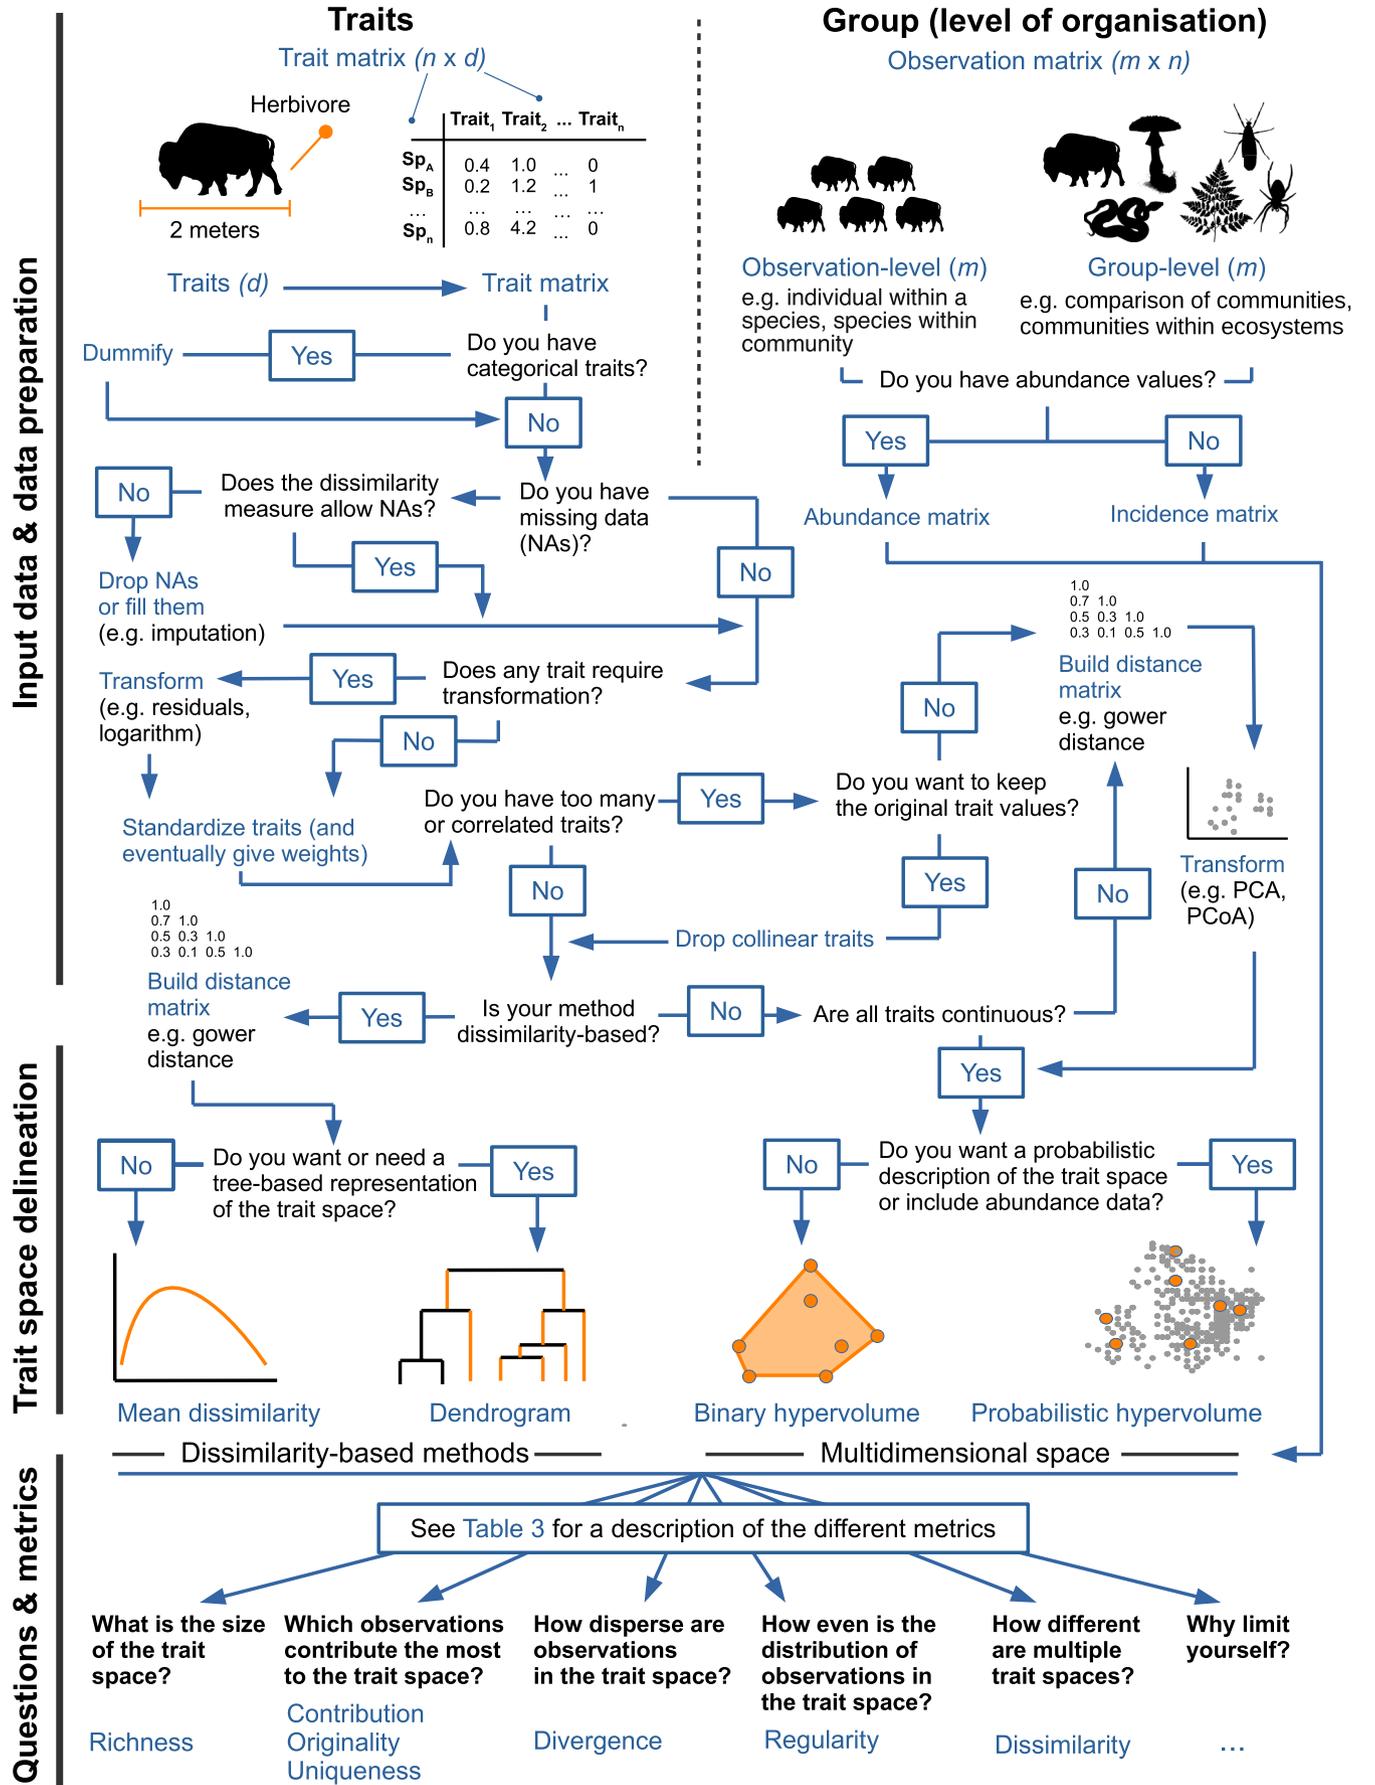

regularity of the shape of a probabilistic hypervolume. Biologically speaking, regularity is used to examine the degree to which there is an effective use of the entire range of resources available to a given niche space (Mason et al., 2005). When the most abundant species share trait space one would expect a strong filtering of specific traits by the environment. Conversely, more regular spacing of trait values and a lower overlap among the traits of the most abundant species would imply a stronger effect of competitive exclusion (Perronne et al., 2017), although care should be taken when inferring assembly processes from functional diversity patterns (Kraft et al., 2015). A practical example comes from cave ecosystems, where the permanent darkness and the consequent lack of photosynthetic primary producers exert a strong filter that skews the total trait space towards the over-expression of traits of detritivorous and predators (Gibert & Deharveng, 2002) or species employing particular hunting strategies (Cardoso, 2012).

4 | ADDITIONAL CONSIDERATIONS RELEVANT TO FUNCTIONAL DIVERSITY ANALYSES

It is important to remember that the performance of each method and the overall quality of a functional diversity analysis depends on the quality of the experimental design and data. There are several issues concerning data quality and its exploration; we briefly touch upon the most relevant to the analytical framework here discussed (Figure 1).

In exploring any trait matrix, one must be aware that it can be a mixture of different data types (numerical, ordered, fuzzy or categorical traits) that may or may not be correlated. To handle different data types in the same analysis, and depending on the assumptions of the functional diversity method of interest, one may need to standardise traits and transform the matrix with adequate distance measures and/or ordination methods (de Bello, Botta-Dukát, et al., 2021; Carvalho & Cardoso, 2020; Lloyd, 2016; Mouillot et al., 2021). Correlations and graphical tools (e.g. scatterplots) can be used to inspect collinearity and, when appropriate, correlated traits can be dropped or summarised as principal component axes (Carvalho & Cardoso, 2020). Finally, one has also to consider how to handle missing data (Johnson et al., 2021), trait variability (Carmona et al., 2019; De Bello et al., 2011; Wong & Carmona, 2021), and other issues (Palacio et al., 2020; Si et al., 2018).

The number of traits for the trait space delineation is a critical feature as well. As the number of traits increases, multidimensional analyses will be subject to the 'curse of dimensionality' (Bellman, 1957). Dimensionality does not only increase computation

time, but it also affects the properties of the trait space. In a probabilistic hypervolume context, for example, the space occupation becomes sparser and tends to occur towards the boundaries of the hypervolume with increasing dimensionality (Blonder, 2016; Guillerme et al., 2020; Mammola, 2019). Also, hypervolume overlap can only decrease at increasing dimensionality, which directly affects the estimation of between-group metrics and redundancy (Carmona et al., 2016b; Mammola, 2019). Note, however, that this is often a consequence of a real biological feature: since two species can differ in so many traits, they are unlikely to overlap much when a high number of traits is considered.

Ultimately, the choice of the number of traits depends on the overall sample size and the question posed, but there is no univocal agreement on this subject (Díaz et al., 2016; Laughlin, 2014; Legras et al., 2020). For example, analyses on plants suggest that our ability to predict community composition improves by adding new traits, reaching a plateau at four to eight traits depending on the system (Laughlin, 2014); however, when adding too many traits, estimation of functional diversity becomes unfeasible and/or unreliable. Future simulation studies comparing the performance of different techniques with different sample sizes and the number of traits could help to develop more precise guidelines in this sense.

Finally, it is important to mention that a proper treatment of functional diversity analyses often requires using randomisation procedures to compare the observed patterns with null expectations (Gotelli & Graves, 1996). Randomisation procedures are used to infer some particular process and/or to test hypotheses of interest, but also to break the trivial correlation between some functional diversity metrics and species richness. For example, since functional richness often increases as new organisms are included in a group, ecologists frequently perform null models to compare the observed values of functional richness with those that would be expected for the same number of species randomly assembled from the considered species pool (Carmona, Guerrero, et al., 2017; Petchey & Gaston, 2002).

5 | CONCLUSIONS

We here illustrated the emerging consensus on a few, non-overlapping frameworks for delineating the trait space and measuring its properties. Our hope is that this synthesis, by digesting available concepts (Table 1), methods (Table 2) and metrics (Table 3), will offer a practical overview and workflow for streamlining functional diversity analyses (Figure 1). Five take-home messages emerge from this exercise:

1. *Do not mix apples and oranges.* Many studies calculate properties of functional diversity with a cocktail of different methods and metrics. This is the case, for example, of many studies based on the R package `FD`, which estimates richness as the volume of a convex hull, divergence as the distance of the observations to a centroid or centre of gravity, and regularity with a minimum spanning tree (Laliberté & Legendre, 2010; Laliberté et al., 2014; Villéger et al., 2008). Whenever possible, we recommend being consistent by choosing a single method for delineating the trait space (e.g. a functional dendrogram or a multivariate space) and sticking to it for exploring its properties in the dimensions of richness, divergence and regularity. In fact, by using a single method, one can be sure that a similar error and uncertainty applies to all the calculations. Conversely, if using different methods, it may be problematic to disentangle the effect of the ecological process(es) of interest from that of the different algorithms used. The same issue occurs when simultaneously studying functional and phylogenetic diversity with different frameworks (e.g. hypervolumes for the first and phylogenetic trees for the latter). Ideally, we want to remove one level of uncertainty in the results, the one associated with the choice of methods, even if others will necessarily remain.
2. *Be aware of uncertainty.* In an ideal world, by calculating analogous metrics using different methods—for example, the functional richness calculated with a dendrogram or a convex hull—one would reach the same (or convergent) results. However, as emphasised by a few comparative studies across a selection of methods and metrics (Junker et al., 2016; Legras et al., 2020; Mammola & Cardoso, 2020; Mouchet et al., 2010; Wong & Carmona, 2021), this is rarely the case. Discrepancies are partly related to the intrinsic differences of each framework (Table 2), and partly to the scale of analysis and methodological choices on how to handle trait variability (Gentile et al., 2020; Wong & Carmona, 2021), as well as the number of traits considered (Legras et al., 2020). We believe it would be necessary to comprehensively analyse properties of the existing methods using either real-world data or simulations based on different combinations of traits, scales of organisation and input parameters. Until then, it is important to acknowledge that often we do not fully understand what each method and metric is exactly measuring.
3. *Refute parochialism.* There are plenty of functional diversity methods and metrics out there, and many more will likely be developed in the future. While this is certainly disorienting for researchers approaching functional diversity analyses for the first time, choosing between seemingly equally appropriate options remains challenging even for experienced researchers (Cianciaruso et al., 2017). Inevitably, most researchers will tend to stick to their 'pet' approach. Yet, it is important to keep in mind that any analytical choice should always be fine-tuned to the ecological question of interest (Appendix S1) and the pros and cons of each method (Table 2), rather than subjective preferences.
4. *Indulge in the unknown.* The existing breadth of metrics will never allow us to explore all the properties of the distribution of observations in a given trait space and to answer the potentially unlimited number of eco-evolutionary questions. When dealing with novel paradigms and systems, one will often have to develop metrics or functions de novo. If one lacks programming skills, there are tools that can facilitate this task (Guillerme, 2018; McPherson et al., 2018). For example, the `dispRity` framework

(Guillerme, 2018; Guillerme et al., 2020) provides a modular architecture to create and test new metrics tailored to specific datasets and questions.

5. *Make the best out of functional diversity.* Developments in functional diversity are occurring rapidly. If one wants to make the best out of this exciting field of research, it is critical to keep up with the latest literature, but also to navigate the literature of other disciplines to drawn on methods and ideas. In fact, the proper treatment of functional diversity estimation is just one out of the many facets that one should consider. A careful design of the study is pivotal to any investigation of functional diversity; whenever possible, one should adopt a rigorous sampling design to strengthen the validity of the conclusions (Smith et al., 2017). Also, data exploration is a central phase in any analysis (Zuur et al., 2009), and so is a proper hypothesis testing, often achievable via regression-type analyses (Zuur & Ieno, 2016) and null modelling/randomisation procedures (Götzenberger et al., 2016). Only by integrating all these different aspects, one will maximise the usefulness of functional diversity to ecology and beyond.

ACKNOWLEDGEMENTS

Thanks to Benjamin Blonder for comments on an early draft of the manuscript, to Diego Fontaneto for suggestions on the glossary and to Caio Graco Roza for useful discussions on functional diversity methods. Filipa Soares provided useful suggestions for Figure 1.

CONFLICT OF INTEREST

C.P.C. is an Associate Editor of Functional ecology but took no part in the peer-review and decision-making process for this paper.

AUTHORS' CONTRIBUTIONS

S.M. and P.C. conceived the idea; S.M. wrote the first draft and prepared figures; P.C. supervised the work and suggested the framework for Table 3; C.P.C. provided most arguments on trait probability density and dissimilarity-based methods; T.G. provided arguments for different sections, including terminology (Table 1). All authors contributed ideas, bibliographic suggestions and with the writing.
