Cubic, yttria-stabilised hafnia, YSH, ceramics of general formula,  $Y_xHf_{1-x}O_{2-x/2}$ :  $x = 0.15, 0.30$  and  $0.45$  were sintered at  $1650\text{--}1750$  °C and characterised by impedance spectroscopy. All three compositions are primarily oxide ion conductors with a small amount of p-type conductivity that depends on atmospheric conditions and appears to increase with  $x$ . The electronic conductivity is attributed to hole location on under-bonded oxide ions and the absorption of oxygen molecules by oxygen vacancies, both of which occur on substitution of  $Hf^{4+}$  by  $Y^{3+}$ . Composition  $x = 0.15$  has the highest total conductivity and shows curvature in the Arrhenius plot at high temperatures, similar to that of the most conductive yttria-stabilised zirconia.

## Introduction

Yttria-stabilised zirconia, YSZ, and other materials with fluorite-related crystal structures, are oxide ion conductors with principal application as the ceramic electrolyte in electrochemical devices such as: solid oxide fuel cells, SOFCs that are used in power generation; electrolyzers for production of  $H_2$  by water electrolysis; and oxygen gas sensors. These applications require an ionic transport number of unity in order to avoid loss of performance in cell operation and power supplies and to give accurate voltage data when they are used for sensor and transport number measurements.<sup>1–4</sup>

The high levels of oxide ion conductivity are obtained by doping the parent oxide,  $ZrO_2$  with acceptor (lower valence) dopants such as  $Y^{3+}$  or  $Ca^{2+}$ ; charge balance is achieved by oxygen vacancy creation. The resulting compositions are presented in two possible ways, as either a general formula or using oxide molar ratios. The YSZ composition with highest oxide conductivity is 92 mol%  $ZrO_2$ , 8%  $Y_2O_3$ , often referred to as YSZ08, which corresponds to  $x = 0.148$  in the general formula  $Zr_{1-x}Y_xO_{2-x/2}$ . Materials such as YSZ08 have a very wide electrolytic domain of oxide ion conductivity which extends to atmospheres with oxygen partial pressure,  $pO_2$  as low as  $10^{-20}$  atm before n-type conductivity associated with oxygen loss becomes significant.<sup>4–6</sup>

Fluorite-structured doped  $CeO_2$  materials are also good oxide ion conductors but, because of easy reduction of  $Ce^{4+}$  to  $Ce^{3+}$  which introduces mixed conductivity, they do not have the same independence of  $pO_2$  as  $ZrO_2$ -based materials and are

of less use as solid electrolytes.<sup>7</sup>  $HfO_2$ -based materials are also good oxide ion conductors that are stable to reduction but have been less studied. Similar to doped zirconia, the ionic conductivity of rare earth  $R^{+3}$  ( $R = Lu, Ho, Gd, Sm, Yb, Y,$  and  $Sc$ )-doped hafnia decreases and the activation energy increases with increasing radius of dopant ions;  $HfO_2\text{--}Sc_2O_3$  has the highest ionic conductivity at composition 14 mol%  $Sc_2O_3$ .<sup>8</sup> Cubic, fluorite-phase  $HfO_2$ , doped with 6 to 20 mol%  $Y_2O_3$  has maximum oxide ion conductivity at 8 mol%  $Y_2O_3$ .<sup>9</sup> With increasing  $Y_2O_3$  content, the conductivity decrease was attributed to defect clustering and increased number of cation dopant–oxygen vacancy interactions ( $Y'_{Hf} - V_O^{\bullet\bullet}$ ).<sup>5,7</sup>  $Hf_{1-x}Ca_xO_{2-x}$  for  $x = 0.08$  to  $0.17$  and at  $800$  to  $2000$  °C showed maximum conductivity at  $x = 0.12$ .<sup>10</sup>

For application as a solid electrolyte, there is much interest in the  $pO_2$  range over which any electronic conductivity is negligibly small. A transition from the electrolytic domain to a region of dominant p-type electronic conductivity should occur for fluorite-structured materials at high  $pO_2$  but is less-well characterised than the transition to n-type behaviour at low  $pO_2$ , Fig. 1. Probably this is because of the difficulty in obtaining ready access to  $pO_2$  values that span many orders of magnitude above atmospheric pressure. Recently, for YSZ materials, p-type behaviour has been studied in two ways. First, application of a dc bias at the same time as impedance measurements were conducted showed a voltage-dependent conductivity which was enhanced to the extent that, for instance, the electronic transport number of YSZ08 had a value of 0.71 at  $556$  °C with 12 V applied voltage.<sup>11</sup> Second, YSZ compositions with much higher  $x$  values showed a reduction in oxide ion conductivity but at the same time, p-type electronic conductivity was observed that was dependent on both  $pO_2$  and dc bias.<sup>12</sup>

The p-type conductivity in these materials is thermally activated and therefore, the holes are localised rather than delocalised in a conduction band. In many cases, the question

Fig. 1 Schematic conductivity,  $\sigma$ , as a function of oxygen partial pressure,  $pO_2$ .

of the location of holes in oxide electroceramics is either not addressed or is attributed to the presence of unavoidable impurities such as Fe which could oxidise to the  $Fe^{4+}$  state by hole creation. Another possibility is that the holes are located on oxygen. In particular, oxide ions that are in an under-bonded environment associated with either acceptor dopants or sample surfaces and interfaces, are surrounded by an effective amount of positive charge that is less than the value of 2+ required for local electroneutrality<sup>11–14</sup> and are therefore possible locations for holes.

The purpose of this work was to investigate the electrical properties of yttria-stabilised hafnia ceramics. High levels of oxide ion conduction were anticipated, but it was of particular interest to assess whether, and under what conditions, electronic conduction may also occur. It was presumed that YSH materials would be strongly resistant to reduction and not give n-type semi-conduction under standard atmospheric conditions as shown by their suggested use as potentiometric oxygen sensors for liquid sodium,<sup>15</sup> but as yet, there is very little information in the literature about the conditions under which p-type semi-conduction may occur. For solid electrolyte applications, the width of the electrolytic window, Fig. 1, is of fundamental importance, not only at the low  $pO_2$  end associated with the onset of oxygen loss and associated n-type semi-conduction, but also at the high  $pO_2$  end associated with oxidation reactions leading to p-type semi-conduction.

## Experimental

Three compositions of  $Hf_{1-x}Y_xO_{2-x/2}$  with  $x = 0.15, 0.30$  and  $0.45$ , were prepared by conventional solid state synthesis utilizing  $HfO_2$  (98%, Sigma-Aldrich) and  $Y_2O_3$  (99.99%, Alfa Aesar) that were dried before weighing at 1000 and 900 °C, respectively. All samples were hand-mixed in a conventional mortar and pestle with acetone, dried and reacted in alumina crucibles in air at 1300 °C for 10 h. The powders were reground and pressed into pellets, 10 mm diameter, in a uniaxial press at 125 MPa for 2 min. Pellets of  $x = 0.15$  were sintered at 1750 °C for 16 h with heating rate 5 °C  $min^{-1}$  followed by cooling in the furnace to room temperature; pellets of  $x = 0.30, 0.45$  were sintered similarly, but at 1650 °C for 4 days because at higher

0.15, 8.1	5.1151(1)	136.3	9.55	8.89	93
0.30, 17.6	5.1468(4)	138.8	8.83	7.84	89
0.45, 29.0	5.1857(7)	139.4	7.94	6.74	85

temperatures than this, they started to react with the alumina boat and melt; they were therefore heated at lower temperature for a long time in order to have a single phase product. The relative density of pellets, calculated from their dimensions and mass, were 0.93, 0.89 and 0.85 respectively, Table 1.

The reaction products were analyzed at room temperature by X-ray powder diffraction (XRD) on crushed pellets using a Bruker D2 Phaser for phase identification and a Stoe Stadi P Diffractometer, Cu  $K\alpha_1$  radiation for lattice parameter determination over the range  $20^\circ < 2\theta < 90^\circ$  with Si internal standard. A combination of field-emission scanning electron microscopy (FEI inspect F50) and energy-dispersion analysis of X-ray (SEM/EDX) were employed to examine the microstructure of sintered samples. Samples were polished and thermally etched at 80% of their sintering temperature for 30 min before coating with 10 nm of carbon.

Au paste electrodes were coated on opposite pellet faces and dried at 900 °C for 2 h. Impedance spectroscopy (IS) measurements in air over the temperature range 250–800 °C and frequency range 0.01 Hz–1 MHz used a Modulab XM Solartron analyzer and in  $N_2$  or  $O_2$  used a Solartron SI 1260 impedance analyzer (Solartron Analytical Ltd, Farnborough, UK).  $pO_2$  values of the atmospheres used were 1 atm ( $O_2$ ), 0.21 atm (air) and  $\sim 0.01$ – $0.001$  atm ( $N_2$ ). The ac voltage for all measurements was 100 mV and IS data were analysed using Zview software. Impedance data were recorded, separately, on open circuit to correct for the blank, parallel capacitance of the conductivity jig and measuring system and on closed circuit, to correct for series inductance of the cell. Data were corrected separately for overall sample geometry and electrode contact area. This allowed resistances and capacitances to be recorded in resistivity and permittivity units of  $\Omega$  cm and  $F$  cm<sup>-1</sup>, respectively, but additional corrections for grain boundary geometry were not made.

Oxygen ion transport number measurements used a Probo-Stat system (NorECs Norwegian Electro Ceramics AS, Oslo, Norway). Dense ceramics were coated with Pt paste (dried at 900 °C for 2 h) electrodes on opposite faces and sealed to one end of a YSZ tube by a commercial glass frit (KeraGlass ST K02), Fig. 2. Pairs of Pt wires were connected to the outer and inner sample faces, and the outer and inner YSZ tube surfaces; voltages were measured using a Keithley 182 sensitive digital voltmeter (Keithley, Ohio, USA). During measurements, lab air was used as the outer tube atmosphere and flowing  $N_2$  gas (99.998% purity) as the inner tube atmosphere to generate a  $pO_2$  gradient.

Fig. 2 Schematic diagram of the set-up used for oxygen ion transport number measurements.

The voltage between each pair of electrodes is given by:

$$E = t_{\text{ion}} \frac{kT}{4e} \ln \left( \frac{P_{\text{O}_2}^{\text{out}}}{P_{\text{O}_2}^{\text{in}}} \right) \quad (1)$$

$$t_{\text{ion}} = \frac{\sigma_{\text{O}^{2-}}}{\sigma_{\text{total}}} \quad (2)$$

where  $T$  is temperature,  $k$  is Boltzmann's constant,  $e$  is electronic charge,  $t_{\text{ion}}$  is the ion transport number and  $\sigma_{\text{O}^{2-}}$  and  $\sigma_{\text{total}}$  are the oxide ion and total conductivities of the material between the electrodes.

For any set of measurements, the test sample and YSZ tube were at the same temperature and in the same  $p\text{O}_2$  gradient;  $t_{\text{ion}}$  of the test sample was obtained from:

$$t_{\text{ion, sample}} = \frac{E_{\text{sample}}}{E_{\text{YSZ}}} t_{\text{ion, YSZ}} \quad (3)$$

YSZ is considered to be a pure oxide conductor (*i.e.*  $t_{\text{ion, YSZ}} = 1$ ) at high temperatures ( $> 600$  °C) and therefore, the oxygen ion transport number of the test sample was obtained using (3). Measurements were made at 600, 700, and 800 °C; the experimental set-up was equilibrated for 24 h at each temperature before measurements were taken.

## Results

### Phase purity and ceramic microstructure

XRD data for  $x = 0.15$  are shown in Fig. 3(a); similar data were obtained for the other compositions and showed that all were phase-pure by XRD. Data were indexed on a face centred cubic unit cell; the lattice parameter,  $a$ , increased approximately linearly with  $x$ , Fig. 3(b), consistent with expectations from the literature.<sup>9,16</sup> SEM results, Fig. 4(a–c), showed a significant difference between  $x = 0.15$  and  $x = 0.30, 0.45$ . The size of grains decreased and the amount of porosity increased in 0.30, 0.45. These differences are attributed to their lower sintering

Fig. 3 (a) XRD patterns of  $\text{Hf}_{1-x}\text{Y}_x\text{O}_{2-x/2}$   $x = 0.15$ , (b) lattice parameter versus  $x$ .

temperature. Grain sizes are  $\sim 30$ – $50$   $\mu\text{m}$  in 0.15,  $\sim 10$ – $30$   $\mu\text{m}$  in 0.30 and  $5$ – $30$   $\mu\text{m}$  in 0.45. EDS mappings of all compositions indicate homogenous distribution of Hf and Y, Fig. 4(e–i).

### Impedance spectroscopy data

A typical set of impedance data, measured in air at 376 °C and plotted in different formats, is shown in Fig. 5 for a pellet of  $x = 0.15$ . A selection of datasets for all three compositions and at different temperatures in the range 275–740 °C, is shown in Fig. S1–S6 (ESI<sup>†</sup>).

The impedance complex plane plot,  $Z^*$ , Fig. 5(a), shows two approximately semicircular arcs at high frequencies and a curved inclined spike at low frequencies. A similar response was observed with all compositions at lower temperatures, Fig. S1, S3 and S5 (ESI<sup>†</sup>). The  $Z''/M''$  spectroscopic plots, Fig. 5(b) show peaks at high frequency in  $Z''$  and  $M''$  and a small peak at intermediate frequencies in  $Z''$ . The high frequency peaks are approximately Debye-like with full width at half maximum, FWHM, close to the value for a Debye peak of 1.14 decades, and peak maxima at similar frequencies, both of which indicate a good degree of electrical homogeneity in the bulk response.

$C'$  data, Fig. 5(c), show evidence of a high-frequency plateau,  $C_1$ , of value  $\sim 2$  pF, which corresponds to a permittivity,  $\epsilon'$ , value of 22.6 calculated from:

$$\epsilon' = C_1/e_0 \quad (4)$$

and attributed to the bulk response; the permittivity of free space ( $e_0$ ) is  $8.854 \times 10^{-14}$  F  $\text{cm}^{-1}$ .

The  $C'$  values increase with decreasing frequency, Fig. 5(c), with some evidence for a poorly-resolved intermediate plateau,  $C_2$ , at  $\sim 6$  pF, corresponding to a permittivity of  $\sim 70$ . This value is much smaller than expected for a typical grain boundary or surface layer impedance. A similar capacitance has been seen in samples of both yttria- and calcia-stabilised zirconia<sup>17,18</sup> and attributed to the presence of dipoles created by oxygen

Fig. 4 Secondary electron images and EDX maps of polished, thermally etched (a, d and e)  $x = 0.15$ , (b, f and g)  $x = 0.30$  and (c, h and i)  $x = 0.45$ .

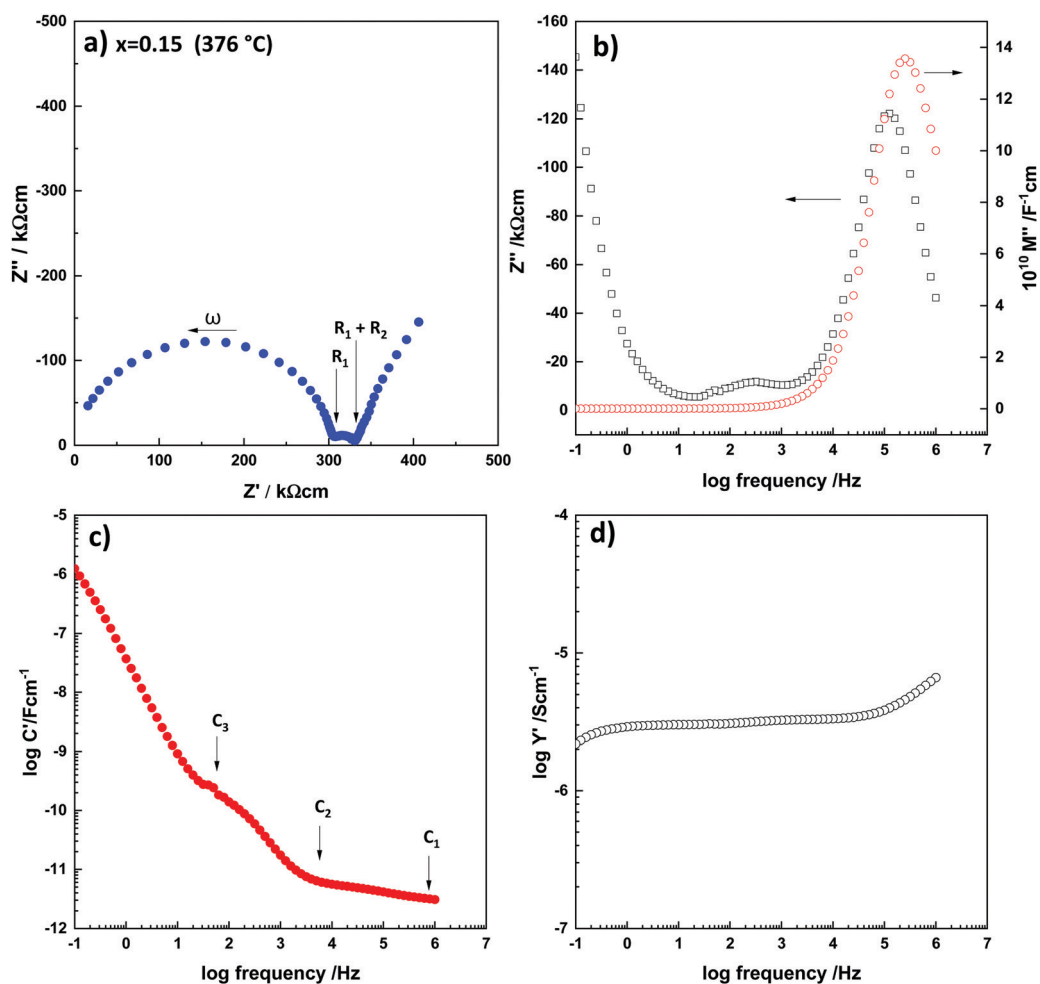

Fig. 5 (a) Complex plane plot ( $Z^*$ ) and spectroscopic plots of (b)  $Z''/M''$ , (c)  $C'$  and (d)  $Y'$  of  $x = 0.15$  in air at  $376\text{ }^\circ\text{C}$ .

vacancy-yttrium/calcium dopant pairs. These dipoles do not contribute to the long range conductivity but are in evidence in the impedance data at high ac frequencies.

A poorly-resolved, low frequency  $C'$  plateau,  $C_3$ , is seen at  $0.1\text{ nF cm}^{-1}$  which corresponds to the small, intermediate frequency arc in  $Z^*$ , Fig. 5(a) and is attributed to a grain

boundary impedance. At still lower frequencies, the highest values of  $C'$ ,  $\geq 1 \mu\text{F}$ , Fig. 5(c) correspond to the low frequency spike in (a) and are attributed to the electrode-sample interface at which oxide ion blocking forms a double-layer capacitance. The curvature of the spike at lowest frequencies Fig. 5(a) indicates that the capacitance is not completely blocking, however, but is in parallel with a resistance that represents a combination of a small amount of electronic conduction through the sample and/or redox processes involved in charge transfer of oxygen across the electrode-sample interfaces. At higher temperatures, especially for  $x = 0.15$ , Fig. S2 (ESI<sup>†</sup>),  $C'$  data show a poorly-resolved plateau around  $10 \mu\text{F}$  but continue to rise to  $\geq 200 \mu\text{F}$  at  $0.1 \text{ Hz}$ . In addition, low frequency  $Z^*$  plots, Fig. S1(d and e) (ESI<sup>†</sup>) show the emergence of a second arc in the low frequency part of the impedance response which indicates a more complex nature of the sample-electrode interface impedances and probably includes a Warburg diffusion impedance associated with diffusion of  $\text{O}_2$  molecules through the metal electrode and towards/away from the interfaces.

$Y'$  data show two overlapping plateaux at intermediate frequency of which the lower frequency plateau corresponds to the total conductivity Fig. 5(d). At high frequencies, the onset of a power law dispersion is seen and is attributed to Jonscher Power Law behaviour which is a common feature of materials that are ionic and/or electronic hopping conductors.

Impedance data of  $x = 0.30$  and  $0.45$  were similar to those of  $x = 0.15$ , but with two key differences, especially at higher temperatures where the low frequency impedance effects are seen more clearly, Fig. 6 and Fig. S3, S5 (ESI<sup>†</sup>). First, the low frequency spike turned into a small arc for the composition of highest  $\text{Y}^{3+}$  content,  $x = 0.45$ . This effect was much more noticeable than the changes in curvature seen with  $x = 0.15$ . Second, with increasing  $\text{Y}^{3+}$  content, capacitance data, Fig. 6(d), show a noticeable reduction in value at low frequencies, indicating that charge transfer at the double-layer interface is no longer predominant. This effect is interpreted as demonstrating the onset of electronic conduction with increasing  $\text{Y}^{3+}$  content in YSH and is similar to results reported for YSZ ceramics of high Y content.<sup>12</sup>

Fig. 6 Complex plane plots ( $Z^*$ ) for (a)  $x = 0.15$ , (b)  $x = 0.30$ , (c)  $x = 0.45$  and (d)  $C'$  spectroscopic plots, measured in air.

From impedance data such as those shown in Fig. 5 and 6, values for bulk, grain boundary and total conductivities were extracted and are shown as Arrhenius plots in Fig. 7. In all three cases, the grain boundary resistance is much smaller than the bulk resistance and therefore the total conductivities in Fig. 7(a) approximate to the bulk conductivities.  $x = 0.15$  shows a higher conductivity, by  $\sim 1$  order of magnitude, than 0.30, 0.45. The Arrhenius plots for bulk and total conductivities of 0.15 are non-linear Fig. 7(a), which is typical behaviour of yttria-stabilized zirconia, shown for YSZ08 in Fig. 7(a) for comparison.<sup>19</sup> The total conductivity decreases with  $x$ , as has been reported in the literature<sup>9</sup> and is attributed to oxide ions, especially for the lower  $x$  compositions. However, the similarity in Arrhenius plots of 0.30 and 0.45, Fig. 7(a), may be because the ionic conductivity decreases but electronic conductivity increases with  $x$  and the two effects largely cancel to give similar overall conductivities.

The grain boundary conductivities appear to be approximately one order of magnitude higher than the bulk conductivities for all three YSH compositions, Fig. 7(b and c). However, in order to obtain true conductivities, they should be corrected for

grain boundary geometry as follows. The capacitance,  $C$  of a sample or region of a sample is given by:

$$C = \epsilon_0 \epsilon' A d^{-1} \quad (5)$$

where  $A$ ,  $d$  and  $\epsilon'$  are the area, thickness and permittivity of the region. If we assume that  $d$  is the main variable that affects the capacitance of different regions of a sample with a simple brickwork model of grains and grain boundaries in a ceramic, and that grain/grain boundary regions have similar permittivity, we can use values of plateau capacitances in plots such as Fig. 5(c) to estimate grain boundary thicknesses. The capacitance values of plateaux that are attributed to grain boundaries are about two decades larger than bulk capacitances. Since the grain boundary resistances are about one decade smaller than the bulk resistances, the net effect is that grain boundary resistivities are about one decades larger than bulk resistivities.

The electrical microstructure of the ceramics has, therefore, grain boundary resistivities that are much larger than grain resistivities but, because the grain boundaries are thin, the bulk

Fig. 7 (a) Arrhenius plots of total conductivity of  $x = 0.15$ , 0.3 and 0.45 sintered at 1650–1750 °C. Activation energies in eV are shown beside each data set. Data for YSZ08 sintered at 1550 °C for 2 h are included for comparison.<sup>19</sup> (b and c) Arrhenius plots of bulk and grain boundary conductivities. Note: the gb data are not corrected for gb geometry.

resistances dominate the overall sample resistances, as shown in the impedance data in Fig. 5(a) and 6(a-c). We note that, for all three compositions, the grain boundary activation energy,  $E_{gb}$  is significantly greater than that of the bulk,  $E_b$ . The differences in resistivity of the two regions are not simply due to either differences in mobile carrier concentration, or to a constriction resistance model of the grain boundary resistance,<sup>20,21</sup> therefore, but involve either a difference in mobility or a contribution from mobile carrier creation. This may be a consequence of small structural or compositional differences between grain interiors and grain boundaries, although there is no evidence of cation segregation from the EDX maps, Fig. 4.

The effect of  $pO_2$  on impedance data is shown in Fig. 8 and 9. For all three compositions, it is clear that the bulk resistance is lower in  $O_2$  than in  $N_2$ . This indicates that there is an electronic component of the overall conductivity since the level of oxide ion conductivity should be insensitive to  $pO_2$ . Further, the reduction in resistance with increasing  $pO_2$  is indicative of

p-type behaviour since holes are created by absorption and dissociation of oxygen molecules, given ideally as:

The electrode contact resistances decrease greatly with increasing  $pO_2$ , as shown by the decrease in size of the low frequency impedance arc, which reflects the involvement of oxygen molecules in reactions at the sample-electrode interfaces.

In order to obtain accurate resistance values, including for the grain boundary resistance, circuit fitting was carried out as follows. The chosen equivalent circuit that represents the complete range of impedance data is shown in Fig. 8 and 9. It is the same as that proposed by recent accurate modelling of impedance data for YSZ and calcia-stabilized zirconia, CSZ.<sup>17,18</sup> Assessment of the validity of the chosen circuit was performed in different ways: (a) visual examination of experimental and fitted data, utilizing the presentation of data in various

Fig. 8 (a and c) Impedance complex plane plots, (b and d)  $C'$  spectroscopic plots of  $x = 0.15$  measured in dry  $N_2$  and  $O_2$  at 450 and 503 °C, respectively. Experimental data points and fits to the circuits are shown.

Fig. 9 (a and c) Impedance complex plane plots, (b and d)  $C'$  spectroscopic plots for  $x = 0.30$ ,  $x = 0.45$  measured in dry  $N_2$  and  $O_2$  at 554 and 526 °C, respectively showing experimental data and fits.

impedance formalisms, (b) comparison of the fit residuals between experimental and calculated data, (c) examination of the values of the fitted data and their temperature-dependence to determine whether they give realistic values for the electrical property characteristics of the sample.

The proposed circuit, Fig. 8(b and d), is composed of four components. First, a parallel combination of  $R_1$ ,  $CPE_1$  and  $C_1$  to represent the bulk conductivity response which is also in parallel with  $C_0$  and  $R_0$  connected in series to model the dipole contribution to the ac conductivity. Second, a parallel combination of  $R_2$  and  $CPE_2$  that is attributed to the grain boundary impedance. The third and fourth components contain two parallel combinations,  $R_3$ - $CPE_3$  and  $R_4$ - $CPE_4$ , connected in series to represent the sample-electrode impedance.

It was found that this circuit was a 'master circuit', parts of which fitted all the impedance data over a wide range of temperature. Since only a limited range of experimental frequencies was available, (0.1–10<sup>6</sup> Hz), the master circuit was not needed, or able, to fit all the data at every temperature.

Nevertheless, each component in the circuit could be evaluated and component parameters provided for a range of temperatures. Fits are shown Fig. 8, 9 and Fig. S7–S10 (ESI<sup>†</sup>). The residuals indicate good quality of fits, Fig. S7–S10(d and h) (ESI<sup>†</sup>). In some cases, the fits are less good at high and low frequencies; this is attributed to the limited amount of data available at these temperatures to obtain accurate fits, as well as inaccuracies in experimental data at the frequency extremes. Fitted resistance values at two temperatures in both  $N_2$  and  $O_2$  are given in Tables 2 and 3; complete data sets are given in Tables S1 and S2 (ESI<sup>†</sup>).

### Transport number measurements

Results of oxygen transport number measurements are shown for three temperatures in Table 4. The value of  $t_i$  is slightly less than unity for  $x = 0.15$ , decreases with  $x$  at 800 °C, consistent with the  $pO_2$  dependence of the conductivity data shown in Fig. 8, 9 and Tables 2 and 3 and is attributed to the onset of p-type electronic conduction.  $x = 0.15$  is therefore at the

**Table 2** Resistance values of  $x = 0.15$  in dry  $N_2$  and  $O_2$  at two temperatures

Composition	$t_{ion}$ (600 °C)	$t_{ion}$ (700 °C)	$t_{ion}$ (800 °C)
$x = 0.15$	0.86	0.94	0.99
$x = 0.30$	0.79	0.78	0.92
$x = 0.45$	0.93	0.88	0.85

cross-over between the electrolytic and p-type domains under atmospheric conditions. Both  $R_1$  and  $R_2$  decrease with increasing  $pO_2$ , Table 2, and therefore, the conductivity Arrhenius plots for  $x = 0.15$ , Fig. 7, represent a combination of oxide ion and electronic conductivities. Similar effects are seen with  $x = 0.30$ ,  $0.45$ ; the low frequency impedance data also show increasing evidence of electronic conductivity, especially for  $x = 0.45$ . We are unable to comment on the relative activation energies of oxide ion and electronic conduction. As far as we can tell, the two mechanisms of ionic and electronic conduction are entirely independent of each other. Transport measurements are likely to be influenced by ceramic microstructure, which may affect the amount of atmospheric oxygen that can be exchanged with the samples, as well as the different resistances that contribute to the overall electrical properties. We regard the data in Table 4 as indicative rather than quantitative, therefore.

## Discussion

YSH materials with a fluorite structure are majority oxide ion conductors with a small amount of p-type conductivity that is very dependent on atmosphere. Of the three compositions studied here, the oxide ion conductivity is greatest for  $x = 0.15$ , similar to that reported previously.<sup>9</sup> The decrease in oxide ion conductivity at higher  $Y^{3+}$  contents is similar to that seen with YSZ compositions, which is attributed to increased trapping of the mobile oxide ion carriers in defect complexes.<sup>6,12,22,23</sup>

The onset of p-type conductivity with increasing  $Y^{3+}$  content is also similar to that seen with YSZ compositions.<sup>12</sup> The location of the holes in both systems is almost certainly on oxygen since the possibility of impurities such as Fe being present in both systems and to an extent that depends on  $Y^{3+}$  content, is most improbable. In addition, location of holes on Y or Hf, to take them above their usual charge states of  $Y^{3+}$  and  $Hf^{4+}$ , is most unlikely.

As proposed previously,<sup>11,12</sup> holes appear to be located on under-bonded oxide ions that are surrounded by insufficient positive charge to fully stabilize the  $O^{2-}$  ion in the crystal lattice. Such under-bonded oxide ions in the bulk region are associated with the acceptor dopants, in this case  $Y^{3+}$ , which substitutes for  $Hf^{4+}$ . Charge compensation for the acceptor dopants involves creation of oxygen vacancies and these are able to absorb oxygen molecules from the surrounding atmosphere, thereby providing the mechanism for hole creation, eqn (6). Additionally, at sample surfaces and interfaces such as grain boundaries, oxide ions may be under-bonded due to an incomplete coordination arrangement of surrounding cations. Some of the oxide ions, in both bulk and grain boundary regions, may ionise spontaneously giving rise to hole conductivity. They may also ionise easily in response to an increase in  $pO_2$ ,<sup>12</sup> eqn (6), or, as described in other systems, to the application of a dc bias.<sup>11,24,25</sup>

These results raise an interesting question as to the intrinsic stoichiometry of materials such as YSH and YSZ since their oxygen content is variable, albeit by a small amount, depending on the atmospheric conditions. Oxygen non-stoichiometry in transition metal oxides is of course, commonplace and is associated with mixed oxidation states of the metal component. In the present case, by contrast, oxygen is the element that potentially, has a mixed oxidation state. These materials exhibit hopping, p-type semiconductivity and the only realistic location of holes is on oxygen since the cations that are present are already in their highest valence states, *i.e.*  $Hf^{4+}$ ,  $Zr^{4+}$  and  $Y^{3+}$ ; in addition, the holes are not delocalised in a band structure. The possibility of redox-active oxygen in oxides has not been considered seriously by most within the electroceramics and chemistry communities until the recent discoveries of battery charge/discharge mechanisms in certain Na and Li transition metal oxide cathodes for which the observed capacities could not be attributed to the transition metal component alone. Nowadays, there are many examples cited of anion redox activity in battery systems.<sup>26,27</sup>

The present materials have  $O^{2-}$  ions as their principal anions but a small amount of  $O^-$  ions can be created by reaction with atmospheric oxygen leading to oxygen redox activity. The unavoidable conclusion, therefore, is that oxygen in oxides should not be regarded always as an inert packing anion but, in certain circumstances, it can be redox active. The classic ionic oxide  $Al_2O_3$ , provides a recent example of p-type conductivity that was also attributed to redox-active oxygen.<sup>28</sup>

## Conclusions

The ac impedance results of  $Hf_{1-x}Y_xO_{2-x/2}$  (YSH,  $x = 0.15$ ,  $0.30$  and  $0.45$ ) demonstrate clear evidence of oxide ion conduction

with an inclined Warburg spike at low frequency and a capacitance value of  $\geq 10^{-6}$  F cm<sup>-1</sup>. Composition  $x = 0.15$  had a conductivity that was  $\sim 1$  order of magnitude higher than that of  $x = 0.30$  and  $0.45$ . The materials are foremost oxide ion conductors but with increasing  $pO_2$  become p-type mixed conductors. The increase in conductivity with increasing  $pO_2$  is reversible and is attributed to oxygen absorption in the vacancies that are created by charge compensation on substituting Hf<sup>4+</sup> by Y<sup>3+</sup> together with the creation of holes on underbonded oxide ions. The p-type semiconductivity is in parallel with the pre-existing oxide ion conduction. The YSH materials at high temperatures in air are, therefore, located just beyond the high  $pO_2$  limits of the electrolytic domain. They represent the second known example of this effect in the family of stable, fluorite-based oxide ion conductors in which hole location on oxygen is responsible for the p-type behaviour and represent a practical limit on the possible application of such materials as solid electrolytes. The possibility of cross-over between electrolytic and p-type domains is well-recognised in the literature on oxides, but its origin, and especially the location of holes, has been discussed rarely, in contrast to the widely-studied onset of n-type behaviour that is observed at low  $pO_2$  and associated with oxygen loss.
