## Abstract

Sweet sorghum (SS) is an agricultural crop that is produced commercially in Nigeria. The crop has a high biowaste energy in its stalk, which is an attractive source of bioenergy in rural areas where it is produced. The residue-to-produce ratio (RPR) of the crop is 1.25 kg of biowaste for 1 kg of SS produced. The solid residue that results from the crop can be subjected to gasification to produce combustible gases: carbon monoxide (CO), hydrocarbon gases (total hydrocarbons) and hydrogen. The combustible gases can be piped into a burner for heat or into a Compression Ignition (CI) engine for electricity generation. This will enhance energy security as well as energy equity in rural areas in Nigeria and sub-saharan African countries where the crop is also produced. This research was aimed at optimising the gasification of SS stalk residue to maximise the yield of combustible gases from the first stage of the process. The restricted ventilation cone calorimeter method was used to gasify SS stalks on a laboratory scale. The test was carried out at air flow rates per exposed flat surface area of 9, 11.2, 12.9, 14.3, 15.5, 16.3, and 19.2 g/s.m<sup>2</sup> respectively, which controls the gasification rate or power output. The speciation of the gases that evolved from the gasification of the biomass

24 samples was carried out by an FTIR that was calibrated for 60 species. Current uses of  
25 biomass residues in open fire heating generates toxic fine particulate emissions and this work  
26 aimed to show that this was not a greater problem with gasification. A dynamic electrical  
27 mobility particle spectrometer (DMS500) was used to measure the particulate size distribution  
28 and concentration, as an efficient gasifier should not be generating major yields of soot, which  
29 would be a problem for a downstream reciprocating engine. The optimum equivalence ratio  
30 ( $\Phi$ ) for the best energy transfer to the gaseous products was 2.1, which was similar to previous  
31 work on pine using this equipment where the optimum equivalence ratio was 2.8. The hot  
32 gases efficiency at the optimum  $\Phi$  was 81%, which compares well to that of 78% for pine.

33 Key words: biomass, gasification, equivalence ratio, particulate number

64

## 65 **1. Introduction**

66 Sweet sorghum (SS) is a multipurpose agricultural/energy crop that is produced commercially  
67 in Nigeria. It is a multipurpose crop because the grain is used for food while the leaves are  
68 used as animal feed. Currently, in Nigeria, the usual practice is to burn most of the agricultural  
69 crop residues in the open fields preparatory to the next planting season. This practice leads  
70 to enormous wastage of energy and environmental pollution. Furthermore, electricity is not

71 readily available in Nigeria in the rural areas, where agricultural crops and crop residues are  
72 produced.

73 The stalk residue of SS is a potential source for biogas (syngas). The residue-to-produce ratio  
74 (RPR) of the crop is 1.25 [1]. The RPR of the crop is quite high. Therefore, the stalk residue  
75 of sweet sorghum is a potential feedstock for syngas. Biomass gasification produces a  
76 flammable gas from a solid biomass, such as sweet sorghum stalk (SSS) and the gas can be  
77 used for heat or fed to a micro-gas turbine [2] or a diesel electric generator for power  
78 generation. Biomass gasifier efficiencies, as energy in the hot BGG as a proportion of the  
79 energy in the biomass used, range from 62-78% [2]. There is a potential to gasify agricultural  
80 crop residues like SSS and use the resulting syngas for electricity generation in diesel  
81 generators. The aim of this work, therefore, was to optimise the gasification conditions for the  
82 production of bio-gasification gas (BGG) from SSS. Gasification is rich burning of the fuel,  
83 where the products of biomass gasification are CO and hydrogen, with hydrocarbons present  
84 as a gasification inefficiency. Optimisation of the gasifier involves determining the equivalence  
85 ratio that has the highest energy content of the product gases, as well as optimising the  
86 operating temperature for maximum energy transfer.

87 Much of the literature on gasifiers [3-7] is about optimising the production of hydrogen, which  
88 is not the same as optimising the energy conversion efficiency. Steam injection into gasifiers  
89 is used to increase the hydrogen production, but this does not increase the energy content.  
90 Gasifiers designed to produce hydrogen see hydrocarbons as a problem, often referred to as  
91 tars, which are removed from the gas along with their energy content. In this work the aim is  
92 to keep the gasifier outlet gases hot in the transfer to a burner or engine, so that the energy in  
93 hydrocarbons are released and this is key to the high overall energy efficiency demonstrated  
94 in this work. The gasification gas would be used to fuel a diesel electricity generation set, so  
95 that rural areas of Nigeria could have low-cost electricity fuelled by the farm agricultural  
96 residues.

97 Investigations have also been carried out to study the effect of syngas substitution of fossil  
98 diesel on the performance of diesel-syngas dual-fuel Reactivity Controlled Compression  
99 Ignition (RCCI) engines [8-12]. Rith et al. [8] and Kousheshi et al. [9] utilised real syngas in  
100 their investigations while Mahgoub et al. [10], Guo et al. [11] and Olanrewaju et al. [12] utilised  
101 simulated syngas in their investigations. These works confirm the feasibility of the use of  
102 diesel-syngas dual fuel in RCCI engines for power generation. An RCCI engine works by using  
103 the BGG injected into the engine turbocharger inlet, with start of combustion timing controlled  
104 by a diesel or biodiesel pilot injection near TDC.

105 Irshad [13] used the Cone Calorimeter method, used in the present work, with pine wood to  
106 determine the gasifier optimum equivalence ratio,  $\phi$  and thermal efficiency of 2.8 and 78%  
107 respectively. Irshad [14] developed the methodology for using the Cone Calorimeter as a  
108 gasifier using the restricted ventilation enclosure around the solid fuel combustion section of  
109 the equipment. By varying the air supply to the enclosure, the gasification equivalence ratio  
110 could be varied. The methodology of Irshad [13] was used in the present work. The optimum  
111 equivalence ratio and Hot Gases Efficiency (HGE) for the gasification of sweet sorghum stalk  
112 residue were compared to those of other waste agricultural biomasses (grain sorghum stalk,  
113 corn stalk, and pine wood).

114 Gasification involves very rich combustion and a possible problem is that gasification can form  
115 soot, as equilibrium predictions show soot as a gasification product for  $\phi > \sim 3$  [15]. Also, fine  
116 particulate emissions from biomass fire burning (lean combustion) for cooking in African  
117 villages is a health problem due to inhalation of ultra-fine particles. It would be desirable to  
118 show that the gasification of biomass to produce a clean gas fuel solved this health problem  
119 in the use of biomass for direct open fire heat. Emissions of ultra fine particles from the gasifier  
120 would be undesirable, so the Particle Number (PN), Particulate Matter (PM) emissions and  
121 size where the maximum PN occurred were investigated.

122 The particle emissions in ventilation-controlled (rich burning) compartment fires for pine wood  
123 cribs [14] were found to be about 100 mg/m<sup>3</sup>. Johansson et al. [16] reported PM emissions of

124 62 to 180 mg/m<sup>3</sup> for pellet burners (lean burning), similar to the value found for pine cribs in  
125 rich burning compartment fires [14]. Mustafa et al. [15] used the restricted ventilation cone  
126 calorimeter method to investigate the PN emissions for construction pine wood at 19.2 g/(m<sup>2</sup>.s)  
127 air flow and 35 kW/m<sup>2</sup> heat flux. A peak PN concentration of 1x10<sup>10</sup> /cc at a particle diameter  
128 for the peak number of particles at 20 nm was found [15]. Altaher et al. [17] reported a peak  
129 PN of 5x10<sup>8</sup> /cc at 30 nm for the lean combustion of biomass pellets in a biomass heater. This  
130 shows higher particle number and a smaller size for gasification conditions, and this will be  
131 investigated for sweet sorghum in the present work, which will be the first investigation of  
132 gasification of sweet sorghum stalks. It is possible that the BGG when burnt in an engine or  
133 burner has its fine particulate content destroyed, but this was not investigated in the present  
134 work. The BGG gas fine PM content has the potential to foul the air intake system including  
135 the valves and so knowledge on this problem is essential for future practical use of BGG for  
136 clean energy generation as electricity or heat.

## 137 **2. Methodology**

138 The materials used for the gasification tests were sun-dried sweet sorghum stalk residue,  
139 grain sorghum stalk residue and corn stalk residue. The biomass composition analysers used  
140 were Mettler Toledo Thermogravimetric Analyser (TGA)/DSC3+, Thermo Scientific Elemental  
141 Analyser 2000, Parr 6200 bomb calorimeter. The gasification test rig is shown in Fig. 1 and  
142 consisted of the Cone calorimeter, Agilent Data logger, Gaset FTIR gas analyser (CR2000),  
143 portable oxygen analyser, and Cambustion DMS500 particle size analyser. The operational  
144 method in gasification mode was as developed by Irshad [13] and used previously on pine  
145 cribs [2,15].

146

147 Fig. 1 The Cone calorimeter and the associated gas analysers

148 **2.1 Cone calorimeter small scale gasifier**

149 A modified controlled atmosphere cone calorimeter was used, with a sealed air box around  
 150 the burning biomass and the air supply controlled so that the metered equivalence ratio  $\phi_m$   
 151 could be varied by varying the air flow. The original version of this cone calorimeter equipment  
 152 had considerable development before it was used in the present work [13].

153 Insulating fibre board lined the gasification chamber, the internal dimensions of the box were  
 154 0.33 m long, 0.275 m wide and 0.305 m high. A metered flow of air was supplied to the sealed  
 155 box from two openings in the bottom. A calibrated variable area flow meter was used to  
 156 determine the flow rate of air so that the metered equivalence ratio,  $\phi_m$ , of the gasification  
 157 could be controlled. The mode of gasification is usually referred to as fixed bed updraught  
 158 gasification. This is because the biomass to be gasified is solid in its raw form and has a fixed  
 159 location and is not agitated as in some gasifiers, such as fluidised bed gasifiers, which operate  
 160 at constant temperatures throughout the bed. The air flow goes upward from the bottom of the  
 161 test chamber over the test section and up the chimney, so it is an updraught gasifier.  
 162 Commercial gasification or log boilers are all fixed bed gasifiers in the primary stage but can  
 163 be either downdraught, or updraught as in the present experiments and several commercial  
 164 log gasification boilers [2].

165

## 166 2.2 Proximate analysis

167 The inner and outer core samples were obtained by separating them from the stalks of the  
168 biomass residues. Thereafter, size reduction of the whole stalks, inner and outer cores was  
169 done by cryo-milling.

170 The proximate analysis of the tested biomass samples was carried out using the Mettler  
171 Toledo TGA. Nitrogen gas was blown through the analyser at the beginning of the TGA at 50  
172 ml/min. Towards the end of the TGA (in the last 15 minutes), air was blown through the  
173 analyser at 50 ml/min for the oxidation of Fixed Carbon (FC) and ash. The temperature profiles  
174 of the TGA analysis are presented graphically in Figs. A1 to A3. The CHNS-O (elemental)  
175 analysis of the biomass residues was carried out on the Thermo Scientific Elemental Analyser  
176 2000, while fuel characterisation was carried out using the Parr 6200 bomb calorimeter. The  
177 carbon and oxygen balance method of Chan and Zhu [18] was utilised to calculate the  
178 stoichiometric AFR of the biomass from the elemental analysis. The test rig operational rich  
179 equivalence ratio ( $\phi$ ) was determined from the mass loss of the test sample and the metered  
180 air flow into the gasifier. This enabled the gasification AFR (metered AFR) by mass to be  
181 determined. The equivalence ratio of the gasifier was the ratio of the stoichiometric AFR  
182 (determined by carbon balance from the elemental analysis [18]) to the measured AFR  
183 (Equation 1). The metered AFR was determined from Equation 2.

$$184 \quad \phi = \frac{\text{stoichiometric AFR}}{\text{metered AFR}} \quad 1$$

$$185 \quad \text{metered AFR} = \frac{\text{metered air flow, g/s}}{\text{mean mass loss rate, g/s}} \quad 2$$

186 The speciation of the sampled raw gases was carried out using the Gaset heated FTIR  
187 analyser. The concentration of hydrogen in the sampled gas was estimated from the  
188 equilibrium constant ( $K$ ) for the water-gas shift reaction (Equations 3 and 4) [19].

190 
$$K = \frac{[CO_2][H_2]}{[CO][H_2O]}$$

4

191  $[CO_2]$ ,  $[H_2]$ ,  $[CO]$ , and  $[H_2O]$  in Equation 3 represent the concentrations of carbon dioxide,  
192 hydrogen, carbon monoxide, and water vapour, respectively. The value that was used for  $K$   
193 in Equation 4 was 3.5, corresponding to an equilibrium temperature of 1,738 K [18].

### 194 2.3 Sample preparation

195 Fig. 2 (a) and (b) depicts the prepared sweet sorghum stalk residue samples in the sample  
196 holder as well as the transverse section of the stalk residue. The test samples were prepared  
197 by cutting the stalks and stacking them into a 100 x 100 mm sample as depicted in Fig. 2(a).  
198 The composite nature of the stalk residue is depicted in Fig. 2 (b).

201 Fig. 2 Preparation of sweet sorghum stalk residue for the gasification test: (a) Biomass sample  
202 in the sample holder (b) Transverse section of sweet sorghum stalk

### 203 2.4 Test conditions

204 Table 1 shows the air flow conditions for the gasification test. The radiant heat flux that was  
205 used during the test was 25 kW/m<sup>2</sup>. This was lower than the 35 kW/m<sup>2</sup> advocated by Irshad  
206 [12, 13] for pine wood and this was because sweet sorghum released volatiles at a lower  
207 temperature than for pine wood, so the radiant heater in the cone calorimeter was reduced in  
208 power. This is equivalent to operating the gasifier at a lower temperature than for wood  
209 gasification.

210 Table 1 Biomass gasification test conditions

| Air flow rate, lpm | Air flux, g/ (m <sup>2</sup> .s) |
|--------------------|----------------------------------|
| 4.4                | 9.0                              |
| 5.5                | 11.2                             |

| 9.4                | 19.2                             |

211

## 212 **2.5 Heat Release Rate (HRR)**

213 The total or overall HRR (THRR) was determined from the cone calorimeter diluted gas  
214 sample analysis using oxygen consumption calorimetry [20]. The gasification gas emerging  
215 from the exit duct above the cone calorimeter was combusted with the entrained ambient air  
216 used in the cone calorimeter. The diluted sample was analysed for its oxygen content which  
217 was used to determine the overall HRR. FTIR analysis of this sample showed that combustion  
218 was complete and CO and hydrocarbons were very low. The THRR was also obtained by  
219 multiplying the mass loss rate (MLR) by the Higher Heating Value (HHV) of the biomass. There  
220 was good agreement in the two methods.

221 The primary HRR (PHRR) in the gasifier was determined by carbon balance from the dry  
222 oxygen analysis after the FTIR. The dry oxygen was converted to a wet oxygen using the  
223 water vapour measured by the FTIR, the oxygen balance method requires the oxygen to be  
224 on a wet basis for HRR analysis. The difference in the THRR and PHRR is the secondary  
225 HRR (SHRR) which is the maximum HRR in the application that the gas is used for: heat, gas  
226 turbine or diesel engines for power generation, which was the application of the present work.

227

## 228 **2.6 Measurement of the Hot Gases Efficiency (HGE)**

229 The Hot Gases Efficiency (HGE) for the gasification of the biomass was estimated from  
230 Equation 5.

$$231 \quad HGE = \frac{(HHV \text{ of the product gases} + \text{sensible heat of the gases}) \left( \frac{MJ}{kg \text{ biomass}} \right)}{HHV \text{ of the biomass fuel} \left( \frac{MJ}{kg \text{ biomass}} \right)} \quad 5$$

232 The HHV for each of the product gases was obtained by multiplying the HHV of the gaseous  
233 component (MJ/kg species) by the Emission Index (EI) of the species (kg species/kg biomass).  
234 The reference temperature that was used Equation 5 was the room temperature (20 °C). All  
235 the measured species with an energy content had the EI determined and converted to heat  
236 release and then all the heat release values were added together to get the total hydrocarbon  
237 heat release.

## 238 **3. Results and discussion**

### 239 **3.1 Biomass analytical test results**

240 The outer and inner cores shown in Fig. 2b were analysed separately and their weight  
241 percentages are given in Table 2. This shows that the inner core, although having more  
242 volume has lower mass, indicating that the core has a low bulk density for all three biomasses.  
243 The CHNS-O, TGA, and bomb calorimetry test results for the three biomass residues are  
244 presented in Tables 3, 4, and 5 respectively. The gasification parameters (AFR and  $\emptyset$ )  
245 presented in Table 6 for the tested conditions of air flow were estimated from Equations 1 and  
246 2 and the stoichiometric AFR data (Table 5). Table 3 shows that the inner and outer cores  
247 have a similar composition, in spite of the difference in bulk density. All parts of the stems  
248 have a high oxygen content, much higher than for wood and this results in a low stoichiometric  
249 AFR, which means less air is required to achieve the gasification mixtures compared with  
250 wood. The moisture content, Volatile Matter (VM), Fixed Carbon (FC), and ash contents of the  
251 crop residues are given in Table 4 and are quite similar to the two layers, although there is

252 some evidence that the ash is concentrated in the inner layer, which indicates that wind blown  
253 dust ash is not significant as this would accumulate in the outer layers.

254 Fig. 3 shows the TGA results of the tested crop residues. Tables 3, 4, and Fig. 3 (the CHNS-  
255 O test and the TGA results) show that the physical properties of the inner and the outer cores  
256 of the tested biomass residues were quite different. Fig. 3 also shows that the moisture in the  
257 samples began to evaporate at temperatures below the boiling point of water (50 °C to 54 °C).  
258 Liquids are known to evaporate within a wide range of temperatures below their boiling points  
259 when the TGA samples are placed in open crucibles [21]. Fig. 3 shows that the volatile release  
260 had two phases: 70% of the mass released by heating between 200 and 350 °C and 15% of  
261 the mass released as high boiling point organic compounds between 350 and 880 °C. The  
262 first rapid release of flammable volatiles creates the rich mixtures that form the gasification  
263 mixture.

264 The nitrogen contents of the composite stalk residues were estimated by adding the products  
265 of the nitrogen contents of the components of the residue (inner and outer cores) and their  
266 corresponding weight fractions (Table 2). The Fuel Bound Nitrogen (FBN) content of SSS is  
267 high and if this was burnt in open fires would result in high NO emissions. However, in  
268 gasification FBN is converted to N<sub>2</sub> and thus the problem of high NO emissions is avoided.

269 The element per carbon ratio of sweet sorghum, grain sorghum and corn stalks were  
270 estimated from the CHNS-O test results and presented in Table A1.

271 Table 2 Weight percentages of inner and outer cores of the tested residues

| <b>Biomass</b> | <b>Inner core, wt%</b> | <b>Outer core, wt%</b> |
|----------------|------------------------|------------------------|
| Sweet sorghum  | 30.00                  | 70.00                  |
| Grain sorghum  | 25.00                  | 75.00                  |

284

285 Fig. 3 TGA profiles for the tested biomass residues (whole stalks, inner and outer cores)

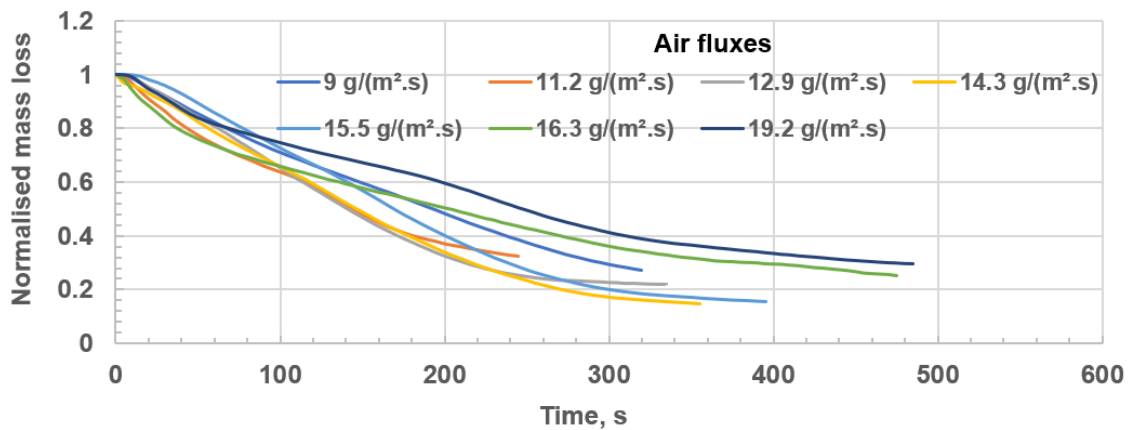

### 286 **3.2 Mass Loss Rate (MLR) profiles for sweet sorghum stalk residues**

287 The normalised mass loss and the Mass Loss Rate (MLR) profiles for the gasification of sweet  
288 sorghum stalk residues at the tested air flow conditions are shown in Figs. 4 and 5 respectively.  
289 Fig. 4 shows that at the end of the test when the flame had gone out there was a remaining  
290 mass that had not been gasified which varied between 30% of the initial biomass mass for  
291  $19.2 \text{ kg}_{\text{air}}/\text{m}^2\text{s}$  to 15% at  $11.2 \text{ kg}_{\text{air}}/\text{m}^2\text{s}$ , which is similar to the fixed carbon of 18% in the TGA  
292 analysis. This was undergoing smoldering combustion as the mass was still reducing slowly  
293 in Fig. 4 and the mass loss rate in Fig. 5 goes to a low value at the end of the test, but not to  
294 zero. Smoldering combustion is a very slow char oxidation rate. It is shown in the energy  
295 analysis of the results that the hot gases efficiency (HGE) of the process is 81% at the optimum  
296  $\Phi$ , but lower for other biomass. It is likely that the inefficiency is due to the char produced not  
297 being efficiently gasified. Also, the energy in char per kg is 1.64 times the energy in the original  
298 biomass, thus if char is not gasified then this will limit the HGE.

299 Four stages (A, B, C and D) were identified during the rich burning of the sweet sorghum  
300 biomass residue, as shown in Fig. 6 for the  $16.3 \text{ g}/(\text{m}^2.\text{s})$  air ventilation condition. The period  
301 of negligible mass loss, during which the gradient of the normalised mass loss profile was  
302 zero, represents the Ignition Delay (ID) for the test (the duration between the test start time  
303 and the auto-ignition of the biomass sample). The ID of the sweet sorghum stalk samples for  
304 the tested conditions ranged from 7 s to 25 s. The auto-ignition of the sample was followed  
305 by a period of rapid loss in mass due to the rapid burning of the biomass sample in the air  
306 inside the compartment at the start of the test (stage A). Stage A was initial lean combustion  
307 using the air in the chamber at the start of the test as well as that supplied to the chamber.  
308 Stage A was followed by the steady state flaming gasification phase (B). This is the steady  
309 state gasification period of the test in terms of steady mass loss rate and relatively constant  
310 HRR as shown in Fig.7. Stage C is the char combustion stage (C) but with some visible flame,  
311 due to CO combustion, and a lower rate of mass loss than the flaming gasification phase B.  
312 The end of stage C was the flameout time (420 s for the  $16.3 \text{ g}/(\text{m}^2.\text{s})$  air flow condition. Stage

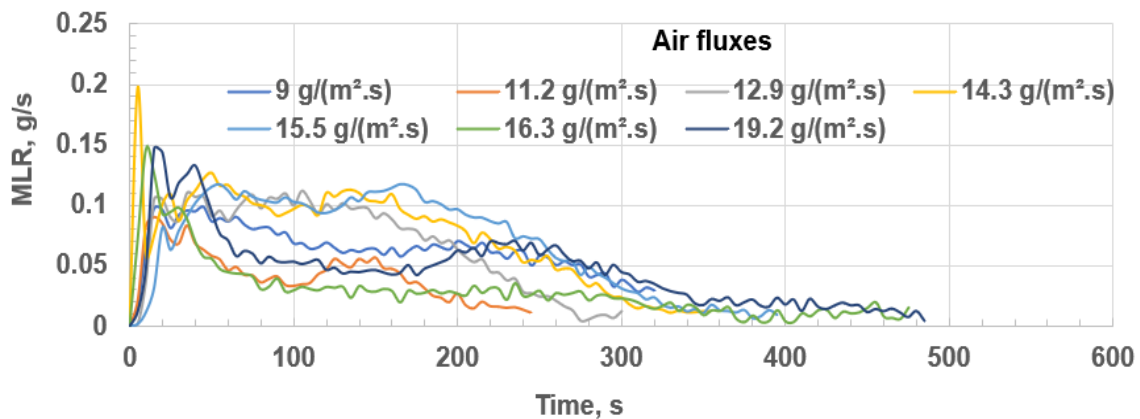

313 D was the smoldering combustion phase giving a mass loss but with no flaming combustion.  
 314 The flame photographs for different stages are shown in Fig. 6 (b), (c), and (d).  
 315 The AFR and the yield of the products of gasification were determined when the gasification  
 316 was at steady state. It is shown later that steady state gasification occurs later when CO and  
 317 THC are roughly constant and this period is about 120 – 220 s. The delay in the establishment  
 318 of steady state gasification conditions is the delay in heat transfer to the biomass sample,  
 319 which releases volatiles as the heat is conducted through the biomass fuel. This fuel heat-up  
 320 period was shown for pine wood by Irshad [13] using imbedded thermocouple, which were not  
 321 practical to attach to the sweet sorghum stalks.

### 334 3.3 Equivalence ratios ( $\phi$ )

335 The measured AFRs and equivalence ratios ( $\phi$ ) for each air flow are shown in Table 6, which  
 336 shows that  $\phi$  decreased as the air flow was increased. This was because the rate of  
 337 consumption of fuel in the gasifier is a linear function of the air flow as for all fuels the HRR is  
 338 close to 3 MJ/kg<sub>air</sub>. Thus, increasing the air flow increases the fuel consumption while the  
 339 oxidation tends towards complete combustion. This makes the gasification zone leaner. Table  
 340 6 shows that increasing the air flow changed the equivalence ratio from 3.6 to 1.4, which is  
 341 the range within which optimum gasification was observed to occur for the investigated  
 342 biomass residues.

343

344 **3.4 Heat Release Rate (HRR) profiles for sweet sorghum stalk residues**

345 The primary and secondary HRR profiles (PHRR and SHRR) for the 9 g/(m<sup>2</sup>.s) test condition  
346 for sweet sorghum stalk is shown in Fig. 7. The peak PHRR in Fig. 7 occurred immediately  
347 after auto-ignition with the initial volatile release burning in the air in the gasifier with a high  
348 HRR. Once the only air available was from the air inlet, the mixture became richer and  
349 combustion flames were replaced by gasification with low PHRR. Fig. 7 also shows the period  
350 of steady state total HRR (+/- 10%) for the 9 g/(m<sup>2</sup>.s) condition was from 65 to 130 s.  
351 Gasification of the exposed top surface of the sample (the outer core) occurred immediately  
352 after the auto-ignition of the sample. The burning of the exposed top outer core exposed the  
353 inner core of the stalks to the flames. After 200 s, (Fig. 7) the inner core was burned up thereby  
354 exposing the outer core at the base of the sample holder. The gasification of the outer core at  
355 the base of the sample holder led to the third PHRR peak. Therefore, the period of steady  
356 state gasification of the composite biomass was carefully delineated as the period between  
357 the end of the gasification of the exposed (top) outer core and the beginning of the gasification  
358 of the outer core at the bottom (after 200 s for the condition shown in Fig. 7). In this manner,  
359 the true steady-state HRR period for the composite material (both outer and inner cores) was  
360 marked out so that the period of gasification of the outer core alone was not erroneously  
361 included in the delineation.

362

363 Fig. 7 PHRR and SHRR profiles for the 9 g/(m<sup>2</sup>.s) test condition (Ø=3.6)

364

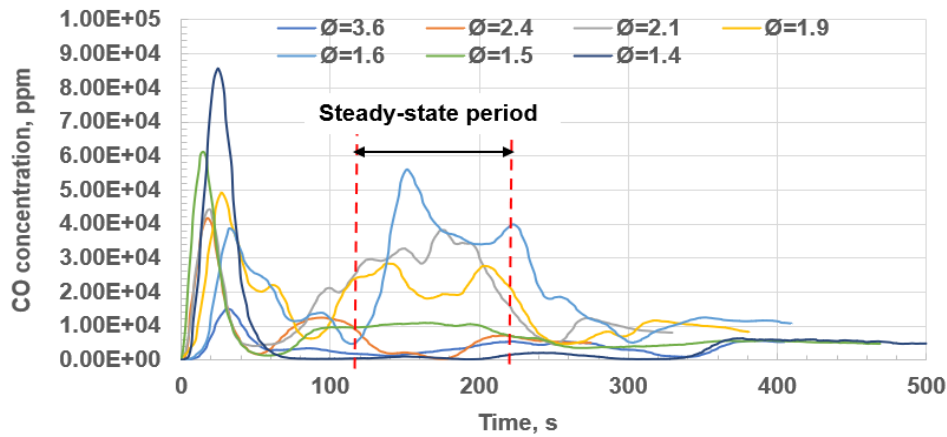

365 Fig. 8 Total Heat Release (THR) profiles of sweet sorghum stalks

366 The Total Heat Release (THR) profiles for all the tested conditions are shown in Fig. 8. The  
 367 duration of the test was different for each of the investigated conditions due to the non-uniform  
 368 diameter of the stalks. The diameter of the stalks ranged from 15-20 mm. The THR for the  
 369 gasification of the sweet sorghum stalks for equivalence ratios ( $\emptyset$ ) between 1.6 and 2.1 were  
 370 relatively high compared to the THR at the other  $\emptyset$  values. This suggested that the optimum  
 371  $\emptyset$  for the gasification of the sweet sorghum stalk would be between 1.6 and 2.1.

### 372 3.5 Evolution of CO and THC during the rich burning of sweet sorghum stalks

373 Figs. 9 and 10 show the evolution of CO and THC (total hydrocarbons) gases from the  
 374 gasification of the sweet sorghum stalk residues. The THC values were calculated from the  
 375 FTIR concentrations of the hydrocarbon compounds (Table A2) by converting the FTIR  
 376 concentrations of the hydrocarbons to their methane equivalents. The FTIR concentration of  
 377 each hydrocarbon compound was converted to the methane equivalent by multiplying the  
 378 measured concentration by the number of carbon atoms in the compound. Thereafter, the  
 379 methane equivalents of the species for each of the tested air flows/conditions were summed  
 380 up to obtain the THC for the air flow. The spikes in the concentration profiles that occurred  
 381 within the first 50 s of the gasification were as a result of the initial lean combustion at the start,  
 382 as the compartment with the gasification material inside was full of air at the start and it takes  
 383 time before gasification steady state is achieved. This initial lean combustion gave rapid

384 combustion of the test samples immediately after auto-ignition as shown in Fig. 6 (a) and (b)  
385 and in the HRR results in Fig. 7.

386

387 Fig. 9 Evolution of CO from the primary stage of the gasification

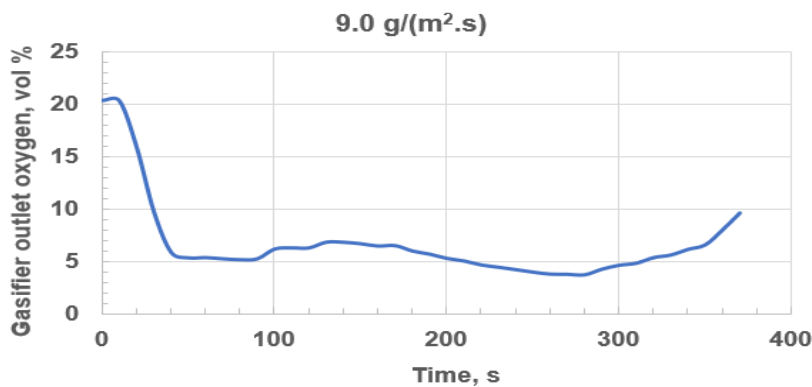

388

389 Fig. 10 Evolution of THC from the primary stage of the gasification

390 The effect of steady state gasification on the evolution of CO and THC gases is shown in Figs.  
391 9 and 10, which show that the highest CO and THC were for  $\text{Ø} = 1.6 - 2.1$ , with lower values  
392 for leaner and richer mixtures. This is the optimum gasification condition which yields the  
393 highest energy content in the biomass gasification gas (BGG) in the period 120 s – 220 s after  
394 the start of the test. This is the steady state gasification period and would be longer if more  
395 mass of sample had been used. The results depicted in Figs. 9 and 10 show that the optimum  
396 gasification condition with the maximum yield of CO and THC was for an air flux of 13 – 14

397 g/ms<sup>2</sup> with an equivalence ratio,  $\phi$ , of about 2. The objective of the gasifier was achieved with  
398 low heat release but good gasification and release of CO, hydrocarbons and hydrogen which  
399 burn in the second stage combustion after the outlet from the gasifier chimney when ambient  
400 air is entrained. During the gasification period oxygen was depleted in the flue, which will be  
401 the same as the oxygen in the gasifier, as shown in Fig. 11.

402

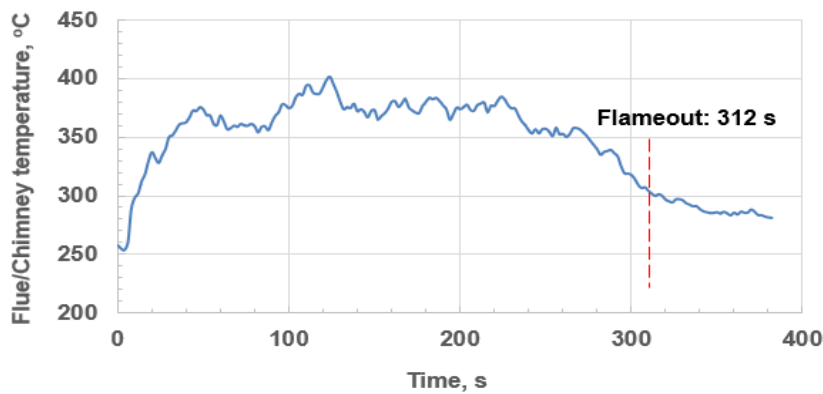

403

404 Fig. 11 Gasifier outlet oxygen as a function of time.

405 Phase C in Fig. 6a, after 300 s had low CO and THC at all air ventilation rates, yet there was  
406 a significant but low mass loss rate, as shown in Fig. 5. This is the char combustion phase  
407 after all the volatiles have been gasified. There was an observable flame in this period, as  
408 shown in Fig. 6d, which would be a CO flame. At the end of the char combustion Phase C, the  
409 flame was observed to go out, but smoldering combustion remained, as shown in Fig. 6d, as  
410 there was a continuing mass loss. There was a transition from gasification near-zero oxygen-  
411 rich combustion to char combustion after 350 s. The increase in oxygen in the char combustion  
412 region showed that the char was not being gasified but was burning in oxygen. This is the key  
413 reason for the inefficient conversion of biomass energy to BGG energy.

414 This change from biomass gasification to char oxidation had an influence on the gasifier exit  
415 temperature as shown in Fig. 12, for the optimum gasification at  $\phi=1.9$ . In the peak gasification  
416 phase from 120 to 220 s, deduced from the CO and THC results, Fig. 12 shows that the  
417 gasifier outlet temperature was constant at the average temperature of 380 °C or 657 K. This

418 is a much lower temperature than the 800 – 900 °C used in many gasifiers [22]. This is because  
419 it is the hydrocarbon volatiles evolved from the biomass that is being gasified initially. After  
420 220 s the mass burn rate decreases due to the start of char combustion in the surplus oxygen  
421 that occurs due to the change of stoichiometric AFR for char compared to the biomass. To  
422 gasify the char phase the temperature in Fig. 12 would be increased, as discussed above, by  
423 reducing the air flow to produce rich char gasification conditions with near-zero oxygen. This  
424 could be achieved in a practical application of batch gasification with the increase in oxygen  
425 signaling a requirement to reduce the air flow until the temperature increased and oxygen was  
426 near-zero.

427

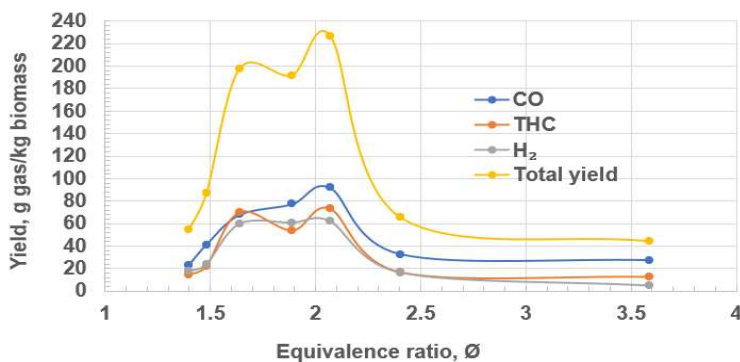

428 Fig. 12 Flue (chimney) temperature profile for the gasification of sweet sorghum stalk residue  
429 at  $\phi=1.9$

430 The slower rate of burning for char gave rise to an increased oxygen level as the gasification  
431 conditions for char are quite different from those for the raw biomass. The oxygen  
432 concentration increased with char combustion due to operation at constant air flow. If char is  
433 assumed to be pure carbon then the stoichiometric AFR is 11.5/1 which is much higher than  
434 for the sweet sorghum biomass which was 4.6. For a constant air flow this means that the char  
435 mass burn rate would be lower than for the biomass by a factor of 2.5, but the HRR would be  
436 similar as the GCV for Char is 29.6 MJ/kg compared with 18.0 for sweet sorghum. The heat  
437 release per kg of air for char is 2.57 MJ/kg<sub>air</sub> and 4.0 MJ/kg<sub>air</sub> for sweet sorghum, so if the air  
438 flow is constant to the gasifier then char mass burn rate will be 63% lower than for sweet

439 sorghum for the same heat release in MJ, as shown in Fig. 5 for the char burning Phase C.  
440 However, the mass burn rate in the char phase is much lower than 63% of that in the biomass  
441 gasification phase and this is because the optimum gasification temperature for char is higher  
442 than for biomass at about 1,200 K. The effect of this is to make the gasification conditions for  
443 char leaner and thus less optimum for the generation of CO and hydrogen. This is why the CO  
444 is lower in Fig. 9 in the char burning phase. For the gasifier to convert char to CO it needs to  
445 operate richer with reduced air flow, also water injection helps the conversion of carbon to  
446 hydrogen, as well as CO to hydrogen and CO<sub>2</sub>. For batch gasification of biomass, future work  
447 will investigate reducing the air flow in the char gasification stage and increasing the hydrogen  
448 yield with water injection into the residual char.

### 449 **3.6 Estimation of the optimum $\phi$ for the gasification of sweet sorghum stalk** 450 **residue**

451 The yields of the combustible gases (CO, H<sub>2</sub>, and THC) that were evolved during the  
452 gasification of the crop residues were averaged at steady state for the air fluxes that were  
453 tested. The THC yield was computed in terms of the methane (CH<sub>4</sub>) equivalent of the emitted  
454 hydrocarbon gases. The estimated yields (in g/kg biomass residue) as well as the flow rates  
455 of the combustible gases were plotted against the equivalence ratios as shown in Figs. 13 and  
456 14 respectively.

457

458 Fig. 13 Yield of combustible gases from the gasification of sweet sorghum stalk residue

459

460 Fig. 14 Flow rate of combustible gases from the gasification of sweet sorghum stalk residue

461 Fig. 13 and 14 show that the maximum yield and flow rate of the combustible gases occurred  
 462 at  $\phi=2.05$  ( $\approx 2.1$ ). The total hydrocarbons were an important part of the gas composition and  
 463 energy transfer. It is important to keep the outlet gases hot in the transfer pipes to an engine  
 464 or burner, so as to avoid condensation of the hydrocarbons and formation of tars. Many more  
 465 traditional gasification systems have a poor HGE due to the loss of the tars, they see the tars  
 466 as a problem not as an important part of the energy transfer from the biomass. The estimated  
 467 optimum value of  $\phi$  (2.1) for the gasification of sweet sorghum stalk residue compared well to  
 468 the value that was estimated for pine wood (2.8) by Irshad [2, 12, 13] using the same  
 469 equipment. The optimum gasification  $\phi$  for sweet sorghum also compared well to the  
 470 experimentally determined values for the stalks of grain sorghum and corn (1.7 and 1.9  
 471 respectively).

472 The Calorific Value (Cv), average molecular weight, and viscosity of the BGG at the optimum  
 473  $\phi$  for sweet sorghum stalk were 6.2 MJ/kg, 19.8 kg/kgmol, and  $2.32 \times 10^{-5}$  Pa.s respectively.

474 The composition of the BGG at steady state biomass gasification for the three biomass  
 475 residues investigated is given in Table 7 and these are comparable to those in the literature  
 476 for biomass gasifiers [2].

477

481

482 **3.6.1 Investigation of the relationship between the Maximum Flue Temperature (MFT),**  
 483 **Char Gasification Flue Temperature (CGFT), and equivalence ratio**

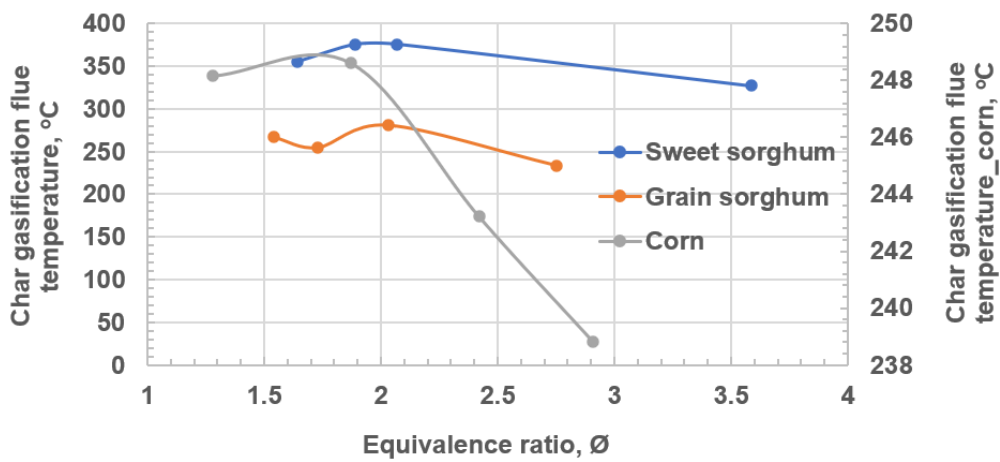

484 The maximum temperature of the flue/chimney (MFT) and the steady state Char Gasification  
 485 Flue Temperature (CGFT) for the tested air flows were determined from the gasifier outlet  
 486 chimney temperature profiles. The temperature profile of the chimney for the gasification of  
 487 the sweet sorghum stalk residue for the 14.3 g/(m<sup>2</sup>.s) air flow condition is shown in Fig. 12.  
 488 The MFT for the condition (401 °C) occurred 124 s after the start of the test while the flameout  
 489 time was 312 s. The steady state temperature of the flue during char gasification (CGFT) was  
 490 about 380 °C. The MFT and the steady state CGFT values were plotted against the  
 491 equivalence ratios as shown in Figs. 15 and 16 for the stalk residues of sweet sorghum, grain  
 492 sorghum, and corn.

493

494

495 Fig. 15 Relationship between the Maximum Flue Temperature and equivalence ratio ( $\emptyset$ )

496

497 Fig. 16 Relationship between the Char Gasification Flue Temperature (CGFT) and  
 498 equivalence ratio.

499 Figs. 15 and 16, and Table 8 show that the MFT and the maximum steady state CGFT for the  
 500 crop residues occurred at  $\emptyset$  values that were approximately equal to the estimated optimum  
 501 equivalence ratios for the tested crop wastes in Table 6. Therefore, the optimum equivalence  
 502 ratio can be achieved in the biomass gasifier (designed for automatic operation) through  
 503 temperature control by adjusting the air flow to achieve the MFT for the biomass (Fig. 16).

504

505

506

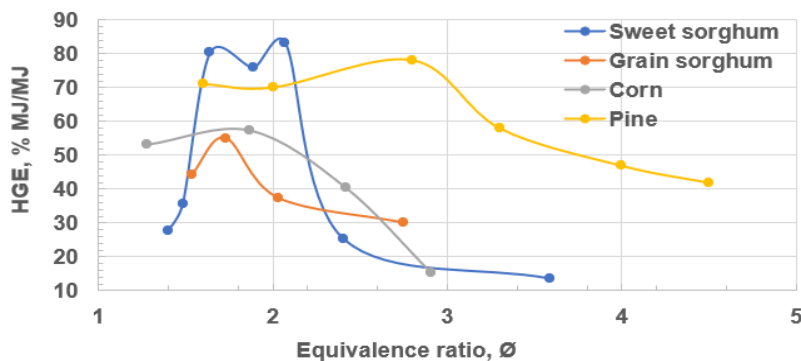

507 Table 8 Relationship between the Maximum Flue Temperature (MFT), Char Gasification Flue  
 508 Temperature (CGFT), and equivalence ratio

| Biomass stalk | MFT, °C | CGFT, °C | Optimum $\emptyset$ | $\emptyset$ at peak temperature |      |
|---------------|---------|----------|---------------------|---------------------------------|------|
|               |         |          |                     | MFT                             | CGFT |
| Sweet sorghum | 401     | 375      | 2.1                 | 1.9                             | 1.9  |
| Grain sorghum | 340     | 280      | 1.7                 | 1.7                             | 2    |
| Corn          | 337     | 249      | 1.9                 | 2.2                             | 1.8  |

509

### 510 3.6.2 Hot Gases Efficiency (HGE)

511 The Hot Gases Efficiency (HGE) of the investigated sweet sorghum stalk samples was  
 512 estimated at the tested conditions from Equation 5. The HGE values were also estimated for  
 513 the stalk residues of grain sorghum and corn. Fig. 17 compares the estimated HGEs to the  
 514 HGE for pine wood. The estimated (maximum) HGE for sweet sorghum stalk residue in this  
 515 work was 81% while the maximum HGE for grain sorghum and corn stalk residues were 52%  
 516 and 46% respectively. The estimated HGE of 81% for sweet sorghum stalk residue falls within  
 517 the top end of the range in the literature [2]. To improve these efficiencies the gasification of  
 518 the residual char would have to be achieved.

519

520 Fig. 17 Comparison of Hot Gases Efficiencies (HGE) of sweet sorghum stalk residue to other  
 521 biomass

522

523 **3.7 Particulate emissions from the gasification of sweet sorghum stalk residue**

524 The Particulate Matter (PM) distributions for the gasification of sweet sorghum stalk residue  
525 at the tested conditions were estimated from the measured Particle Number (PN) distributions.  
526 The PM distributions were estimated at steady state after the measured data were corrected  
527 for dilution. The particles were assumed to be spherical with a particle density equal to that of  
528 carbon at 1,000 kg/m<sup>3</sup> (a common assumption in particle number to mass conversions).

529 **3.7.1 Particle Number (PN) and Particulate Matter (PM) distributions for the gasification**  
530 **of sweet sorghum stalk residue**

531 The Particle Number (PN) and Particulate Matter (PM) distributions for the tested conditions  
532 are given in Fig. 18 (a) and (b). Fig. 18 (a) shows that the tested conditions had PN peaks in  
533 the nanoparticles range (Dp < 30 nm). Generally, the observed peak PN concentrations  
534 (number of particles per cubic centimeter) in this work for the gasification of the stalk residue  
535 of sweet sorghum were much lower than the concentration that was reported for pine wood  
536 by Mustafa et al. [15] (1x10<sup>10</sup> /cc). However, the peak PN concentration that was reported by  
537 Altaher et al. [17] (5x10<sup>8</sup> /cc at 30 nm) for the combustion of biomass pellet falls within the  
538 range of the peak PN concentrations for the gasification of sweet sorghum stalk residue  
539 (7.2x10<sup>6</sup> - 7.8x10<sup>8</sup> /cc).

540

(a)

(b)

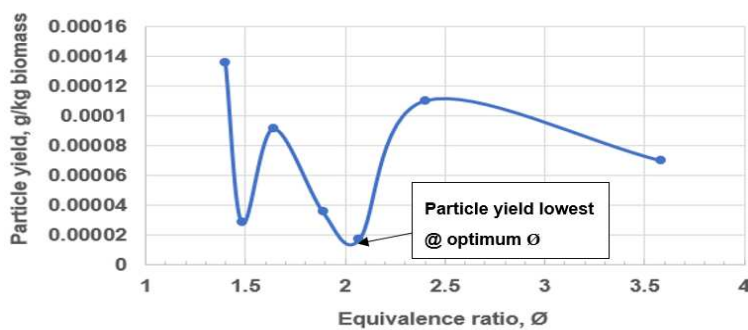

541

542 Fig. 18 Comparison of PN and PM emissions for the tested air flows: (a) PN emissions for the  
543 tested air flows (b) PM emissions for the tested air flows

544 Mustafa et al. [15] reported for pine wood gasification an accumulation mode peak at 200 nm  
545  $D_p$  which compared well to the observed accumulation mode  $D_p$  for the gasification of sweet  
546 sorghum stalk residue at 9, 11.2, and 19.2  $g/(m^2.s)$  air flux conditions. Mustafa et al. [15] used  
547 the same method (Cone calorimeter) that was used in the current work in their investigation.  
548 Gaegauf et al. [23] reported that particles with  $D_p > 300$  nm do not contribute substantially to  
549 total PN emission rate. The authors' report is in agreement with the PN results in the current  
550 work as Fig. 18 shows that the prominent PN peaks of the investigated modes occurred when  
551  $D_p$  was  $< 300$  nm. Fig. 18 shows that the peak PN resulted mostly from nanoparticles with  $D_p$   
552  $< 30$  nm while the peak PM resulted from the fine particles. The fine particles are particles with  
553  $D_p$  between 100 nm and 2.5  $\mu m$  [24]. This 30 nm particle size range is that of the greatest  
554 health hazard on fine particles in the atmosphere and so this could be a source of combustion-  
555 derived nanoparticles, if the diesel engine or burner did not destroy the particles by combustion  
556 in oxidation reactions in the flames in the engine.

### 557 3.7.2 Particulate yield

558 The values for the particulate yield (in g particles/kg biomass) at the tested conditions for the  
559 gasification of sweet sorghum stalk were estimated from the measured PN distributions. Fig.  
560 19 shows that the yield of particulates was lowest at the estimated optimum equivalence ratio  
561 (2.1).

562

563 Fig. 19 Particulate yield as a function of equivalence ratio for the gasification sweet sorghum  
564 stalk residue

565 Johansson et al. [16] reported PM emissions of 62 to 180 mg/m<sup>3</sup> for pellet burners. However,  
566 in the current work, the range of PM emissions for the gasification of sweet sorghum stalk  
567 residue for the tested conditions was 104 to 730 mg/m<sup>3</sup>. The observed disparity in the PM  
568 results in the current work and the result in literature can be attributed to the peculiar composite  
569 nature of the sweet sorghum stalks. Also, the sweet sorghum stalks were not pelletised prior  
570 to the gasification test. The reported particle emission in ventilation-controlled compartment  
571 fires for wood fires by Andrews et al. [25] (100 mg/m<sup>3</sup>) compared well to the particle emission  
572 of 104 mg/m<sup>3</sup> for the 12.9 g/(m<sup>2</sup>.s) air flow condition in this work (the optimum condition). This  
573 comparison is a little unfair to the gasifier gases as in a burner application air would be added  
574 and a downstream flame achieved that would burn most of the particles from the gasification  
575 stage. Similarly for diesel engine applications the engine would consume the particles as apart  
576 from ash the particles will all burn.

### 577 **3.8 Explosive risk of syngas-air mixtures**

578 Two parameters that are commonly used to characterise the explosive behaviour of syngas-  
579 air mixtures are the maximum explosion pressure and the maximum rate of pressure rise. The  
580 results presented by Xie et al. [26] on the explosion behaviour of syngas (CO/H<sub>2</sub> 50:50)-air  
581 mixture show that stoichiometric and near-stoichiometric mixtures have relatively high  
582 maximum explosion pressures (the explosion pressure peaked within equivalence ratio values  
583 between 1 and 1.2). Also, when diluent gases (CO<sub>2</sub> and H<sub>2</sub>O) were added to the initial CO/H<sub>2</sub>  
584 50:50 syngas, the maximum pressure decreased (the explosion pressure decreased as the  
585 concentration of the diluent gases increased). The maximum rate of pressure rise was  
586 reported to increase as the equivalence ratio increased. The authors reported the opposite  
587 trend for the maximum rate of pressure rise when the concentrations of the diluent gases were  
588 increased.

589 Table 6 shows that the equivalence ratios of the gas mixtures for the tested conditions were  
590 > 1.2. The gasification products in Table 7 also contain diluent gases (CO<sub>2</sub> and H<sub>2</sub>O).  
591 Therefore, considering the results about the explosive behaviour of syngas in literature, it can

592 be inferred that during storage or usage in CI engines, the explosive risk of the gas in Table 7  
593 with relatively high oxygen content will be low.

#### 594 **4. Conclusion**

595 The Heat Release Rate (HRR) and particulate emission during the gasification of sweet  
596 sorghum stalk were investigated in the current work by the restricted ventilation Cone  
597 calorimeter method. The optimum gasification conditions for sweet sorghum stalk residue  
598 were also determined.

599 The optimum air flux, equivalence ratio,  $\phi$  and HGE for the gasification of sweet sorghum stalk  
600 residue were 12.9 g/m<sup>2</sup>.s, 2.1 and 81% respectively. The optimum  $\phi$  and HGE values for the  
601 investigated biomass residue (sweet sorghum stalk) compared well to the estimated value of  
602 2.8 and 78% for pine wood. The Maximum Flue Temperature (MFT) and the maximum steady  
603 state Char Gasification Flue Temperature (CGFT) for the tested crop residues occurred at  $\phi$   
604 values that were approximately equal to the estimated optimum equivalence ratios for the  
605 residues. At constant air flow, the rate of combustion of the char that resulted from the  
606 gasification of the biomass was slower than the rate of gasification of the original biomass  
607 residue. This led to relatively lean combustion and low generation of CO during the char  
608 combustion phase. The efficiency of char gasification in fixed bed biomass gasifiers can be  
609 improved by reducing the flow rate of air to achieve rich burning conditions for char.

610 The results of the investigation showed that the peak PN emissions for the gasification of  
611 sweet sorghum stalk residue occurred in the nanoparticles diameter range ( $D_p < 30$  nm) at  
612 the tested conditions. However, the yield of the particles was lowest at the optimum  $\phi$   
613 condition. Particles with  $D_p > 300$  nm did not contribute significantly to the PN emissions from  
614 the gasification of sweet sorghum stalk residue.
