1 **Do mariculture products offer better environment and nutritional** 2 **choices compared to land-based protein products?**

3 **Abstract:** Mariculture products are generally deemed to have less negative environmental
4 externalities and more nutrient content, and are therefore a promising food substitute for land-
5 based protein products (LPPs). China is the world's largest mariculture producer, with 66% of
6 global production share in 2018. However, different categories of mariculture products have
7 varied nutrient composition and environmental impacts, and ignoring such heterogeneity
8 potentially misleads policy decision making in mariculture development in China. Here, we
9 compare the environmental and nutritional performance of 28 mariculture products with 7 LPPs
10 produced in China. Our results show that although mariculture products are more environmentally
11 friendly than LPPs on the whole, not all mariculture products have better nutrition-environmental
12 performance than LPPs. Only 17 out of 28 mariculture products, mainly shellfish and fish, are
13 found to be both nutritionally and environmentally more friendly than LPPs. Shellfish are
14 promising substitutes for LPPs due to their minor environmental impact, higher nutrient density,
15 greater production volume and lower average price compared with other mariculture products.
16 However, upper dietary limits on daily intake of shellfish due to potential overconsumption of
17 certain micronutrients must also be considered. We also found mariculture derived fish have no
18 distinct environmental, nutritional or cost benefits over some LPPs, such as egg and chicken. The
19 current structure of the mariculture industry in China may be optimized by expanding the
20 production of nutrient-rich mariculture products with low environmental impact and affordable
21 price.

22 **Keywords:** mariculture products, land-based protein products (LPPs), water footprint, nitrogen
23 footprint, nutrient density.

24 **1. Introduction**

25 Under the UN's medium growth scenario global population is expected to reach 9.7 billion
26 by 2050 (UN, 2019). The concurrent demand for food and nutrition will lead to huge pressure on
27 natural resources and the environment on a global scale (Tilman et al., 2017; FAO, 2020; Singh et
28 al., 2021; Froehlich et al., 2018). Current protein supply is dominated by land-based protein
29 products (LPPs), which is one of the main causes of environmental damage and climate change
30 (Hilborn et al., 2018). The production of LPPs emits 19-29% of global greenhouse gas emissions
31 (Vermeulen et al., 2012), consumes more than 70% of the world's water resources (Hoekstra and
32 Mekonnen, 2012), and is the main contributor to nitrogen pollution (Mueller and Lassaletta,
33 2020). Despite this we fail to meet global nutritional needs (Golden et al., 2021); globally 820
34 million people are undernourished (Willett et al., 2020), and 30% of the population fall short of at
35 least one micronutrient in their diet (DIPR, 2020).

36 Seafood is rich in micronutrients and is generally regarded as conferring lower levels of
37 environmental stress than LPPs (Golden et al., 2021; Stentiford et al., 2020; Liu et al., 2018).
38 According to recent studies, choosing seafood as an alternative protein source shows promise in
39 meeting nutritional and environmental goals (Vanham et al., 2013; Bogard et al., 2018; Tilman
40 and Clark, 2014). Seafood production may be categorised into two groups, namely capture fishery
41 and mariculture. Capture fishery plays an important role in the global supply of aquatic products,
42 but its expansion has been limited by capacity of the aquatic ecosystem and associated
43 regeneration rates (Foley et al., 2012). The fast expansion of capture fishery has resulted in
44 significant depletion of fish stocks (Golden et al., 2016). In contrast, mariculture has potential for
45 growth due to its comparatively minor impact on marine ecosystems and recent technological
46 advances (Merino et al., 2012). Although only 5% of global protein production is currently
47 derived from mariculture (FAO, 2020; FAO, 2021), the amount of food produced from
48 mariculture is likely to meet 5-19% of the estimated increase in total protein demand of 9.7 billion
49 people in 2050 (Costello et al., 2012).

50 Despite this, concerns have also been raised regarding the environmental and nutritional
51 benefits of mariculture products. Firstly, some mariculture products rely on feed sources from

52 land-based agriculture (Newton and Little, 2018; Little et al., 2018), and the resulting
53 environmental impacts of this cannot be ignored (Froehlich et al., 2018). Secondly, most previous
54 studies treated seafood as a broad category of products to be analyzed together with other food
55 groups (Koehn et al., 2022; Shalders et al., 2022; Wang et al., 2022). Plenty of previous researches
56 have also tended to focus on limited species of mariculture products, mostly fish (Pelletier et al.,
57 2009; Yuan et al., 2017), whilst other species such as shellfish or crustacean are seldom
58 considered (Driscoll et al., 2015; Nanda et al., 2021; Mititelu et al., 2022). To address these
59 concerns, our research approach has been to build a complete list of nutrition and environmental
60 inventories for different mariculture products in order to examine the differences in nutrient
61 content, environmental impact, cost and production.

62 Carbon emissions have usually been the only selected environmental indicator (Madin and
63 Macreadie, 2015), with studies concluding that proteins harvested from the sea have a
64 significantly lower carbon footprint than proteins derived from land animals particularly ruminants
65 (Hilborn et al., 2018; Madin and Macreadie, 2015; Tilman and Clark, 2014; Poore and Nemecek,
66 2018; Godfray et al., 2010). With regard to land use, a recent study concluded that mariculture
67 will continue to rely more on land-based, rather than sea-based, feed sources inputs (Zhang et al.,
68 2022). Given that the key biophysical drivers of crop yield are addition of water and fertiliser,
69 water and nitrogen footprints seem most relevant to crop-based feed production, but are rarely
70 evaluated in mariculture (Mueller et al., 2012).

71 China is the world's leading producer of mariculture products, accounting for around 66% of
72 total global production in 2018 (FAO, 2020; FBCM, 2019). Over the past 20 years, China has
73 produced more than 60 million tons of seafood annually. Mariculture accounted for more than
74 70% of China's seafood output in 2018. Between 1986 and 2018, China's mariculture production
75 increased around 13 times (FBCM, 2019; FAO, 2021). In the present study, we undertook analysis
76 based on China's mariculture. We first evaluated the environmental and nutrient performance of
77 28 different mariculture products using 2018 as the year base. The mariculture products included
78 10 species of fish, 6 species of crustacean, 9 species of shellfish and 3 other classes. The
79 environmental indicators we used included water footprint and nitrogen footprint, and nutrient

80 density was used as the nutritional indicator. We further compared the results from our mariculture
81 product findings with seven selected LPPs. Overall, this analysis is distinguished from previous
82 studies through (1) providing a full list of nutrition and environmental inventories for specific
83 mariculture products; and (2) considering environmental impact indicators most relevant to crop-
84 based feed production i.e., water footprint and nitrogen footprint. We believe our findings help
85 identify opportunities for achieving sustainable diets through mariculture production, contributing
86 to the UN SDG's of Zero Hunger (Goal 2), Responsible Consumption and Production (Goal 12),
87 and Life Below Water (Goal 14).

88 **2. Methods and data**

89 **2.1 Water footprint accounting**

90 The water footprint of a product is the volume of freshwater used to produce the product
91 (Mekonnen and Hoekstra, 2011). The water footprint consists of green water, blue water and grey
92 water. The green water footprint refers to the consumption of rainwater. The blue water footprint
93 refers to the consumption of surface water and groundwater. The grey water footprint refers to the
94 volume of freshwater required to assimilate pollutant loads based on natural background
95 concentrations and existing environmental water quality standards (Hoekstra et al., 2011). Since
96 the grey water footprint aligns with environmental pollution and has some overlap with the
97 contents measured by the nitrogen footprint (Mekonnen and Hoekstra, 2012), the grey water
98 footprint is only shown in the Appendix (Table S6).

99 In this paper, the water footprint of LPPs was derived from the Global Water Footprint
100 Database (Mekonnen and Hoekstra, 2011; Mekonnen and Hoekstra, 2012). The database contains
101 average water footprint of 352 plant products and 106 animal products in China. For mariculture
102 products, the water footprint consists of direct (related to mariculture process) and indirect (related
103 to feed input) water footprint of mariculture. The direct water footprint of mariculture was
104 assumed to be 0, because the water footprint of this study only involved freshwater rather than
105 seawater. We adopted the method recommended by Pahlow et al. (2015) to calculate the indirect
106 water footprint of mariculture, i.e., the water footprint of the feed input for the production of
107 mariculture products.

$$108 \quad WF_{m,i} = \frac{\sum_{f=1}^{n_1} (WF_{i,f} \times \sum_{r=1}^{n_2} \frac{I_{i,f,r}}{n_2}) \times FCR_i \times P_i}{E_i} \quad (1)$$

$$109 \quad WF_{p,i} = WF_{m,i} \times \frac{100}{w_p} \quad (2)$$

$$110 \quad WF_{e,i} = WF_{m,i} \times \frac{100}{w_e} \quad (3)$$

$$111 \quad WF_i = WF_{m,i} \times Y_i \times E_i \quad (4)$$

112 Where $WF_{m,i}$ ($L g^{-1}$) is the water footprint per gram (UWF, the unit is $L g^{-1}$) of
 113 mariculture product i ; $WF_{i,f}$ ($L g^{-1}$) is the UWF of raw material f in the standard feed formula of
 114 mariculture product i ; and n_1 is the number of raw material f in the standard feed formula of
 115 mariculture product i ; $I_{i,f,r}$ ($g g^{-1}$) is the weight of raw material f in the feed formula r of
 116 mariculture product i ; n_2 is the number of feed formula of mariculture product i ; FCR_i is the
 117 feed conversion rate of mariculture product i ; P_i is the feeding ratio of mariculture product i ; E_i
 118 is the edible part of the product, that is, the proportion of uncooked products following removal of
 119 all inedible parts. $WF_{p,i}$ ($L g^{-1}$) is the water footprint per gram of protein of mariculture product
 120 i ; w_p (g) is the protein content per 100g mariculture product i . $WF_{e,i}$ ($L kcal^{-1}$) is the water
 121 footprint per calorie of mariculture product i ; w_p ($kcal$) is the calorie per 100g mariculture
 122 product i . WF_i (m^3) is the total water footprint (TWF, the unit is m^3) of mariculture product i ; Y_i
 123 (kg) is the production of mariculture product i in China in 2018.

124 Feed formulas affect the UWF. Based on the standard feed formula database of the China
 125 Fisheries Data Center (CFDC, 2019), FishBase (WFD, 2019) and patent database (PD, 2019), 167
 126 officially recommended feed formulas were selected to calculate the standard feed formulas for 28
 127 mariculture products (Table S2). We overlooked trace components in the feed formulation due to
 128 lack of data. The UWF of fish meal and fish oil were assumed to be zero (Gephart et al., 2014).

129 The UWF of feed ingredients was obtained from the Global Water Footprint Database (Table
 130 S3) (Aldaya et al., 2012). Our study selected feed ingredients with available green, blue and grey
 131 UWF data of Chinese provinces in 2018, simulated 10,000 times in Monte Carlo in order to
 132 achieve the probability distribution and related statistical parameters.

133 2.2 Nitrogen footprint accounting

134 The nitrogen footprint is defined as the total amount of nitrogen released into the
 135 environment by an entity's consumption and associated food and energy production (Leach et al.,
 136 2012). The nitrogen footprint of food production represents all nitrogen losses along the food
 137 production chain to food consumption (Galloway and Leach, 2016). Here, for plant products, we
 138 only considered four steps of nitrogen flows: 1) the input of new nitrogen, 2) crop production, 3)
 139 crop harvest, and 4) plant food processing. For animal-based products, we considered six steps of
 140 nitrogen flow: 1) the input of new nitrogen, 2) feed production, 3) feed processing, 4) animal
 141 production, 5) animal slaughter, and 6) processing of animal-derived foods. In order to be
 142 consistent with water footprint accounting we didn't consider further nitrogen losses in other
 143 steps, including food consumption.

144 The nitrogen footprint of LPPs was derived from the data set published by Hu et al. (2020),
 145 which contains nitrogen emissions from common agricultural and animal product production
 146 processes (Table S10). The nitrogen footprint of mariculture products was not included in this data
 147 set. Therefore, we calculated the nitrogen footprint per gram (UNF, the unit is g g^{-1}) of feed in
 148 mariculture products, and then calculated the production UNF of mariculture products based on
 149 the coefficient ratio of the production UNF to the UNF from feed:

$$150 \quad NF_{m,i} = \frac{\sum_{f=1}^{n_1} \left(\frac{NF_{i,g}}{NCF_{f,g}} \times \sum_{r=1}^{n_2} \frac{I_{i,f,r}}{n_2} \right) \times FCR_i \times P_i \times NC_i}{E_i} \quad (5)$$

$$151 \quad NF_{p,i} = NF_{m,i} \times \frac{100}{w_p} \quad (6)$$

$$152 \quad NF_{e,i} = NF_{m,i} \times \frac{100}{w_e} \quad (7)$$

$$153 \quad NF_i = NF_{m,i} \times Y_i \times E_i \quad (8)$$

154 Where $NF_{m,i}$ (g g^{-1}) is the UNF of mariculture product i ; $NF_{i,g}$ (g g^{-1}) is the UNF of
 155 primary product g of raw material f in the standard feed formula of mariculture product i ; $NCF_{f,g}$
 156 is the nitrogen conversion coefficient of raw material f and its primary product g (FAO, 2015); n_1
 157 is the number of raw material f in the standard feed formula of mariculture product i ; $I_{i,f,r}$ (g g^{-1})
 158 is the weight of raw material f in the feed formula r of mariculture product i ; n_2 is the number of
 159 feed formula of mariculture product i . FCR_i is the feed conversion rate of mariculture product i ;

160 P_i is the feeding ratio of mariculture product i ; NC_i is the coefficient ratio of the production UNF
 161 of mariculture product i to the UNF from feed (Oita et al., 2016); E_i is the edible part of the
 162 product. $NF_{p,i}$ (g g^{-1}) is the nitrogen footprint per gram of protein of mariculture product i ; w_p
 163 (g) is the protein content per 100g mariculture product i . $NF_{e,i}$ (g kcal^{-1}) is the nitrogen footprint
 164 per calorie of mariculture product i ; w_p (kcal) is the calorie content per 100g mariculture product
 165 i . NF_i (t) is the total nitrogen footprint (TNF, the unit is t) of mariculture product i , and Y_i (kg)
 166 is the output of Chinese mariculture product i in China in 2018.

167 2.3 Nutrient density

168 The nutrient density of mariculture products was quantified according to a nutrient density
 169 scoring method recommended by Hallstrom et al. (2019). The formula used to calculate the
 170 nutrient density score is as follows:

$$171 \quad NDS-A = \sum_{i=1}^x \frac{Nutrient_i}{DRI_i} - \sum_{j=1}^y \frac{Nutrient_j}{MRI_j} \quad (9)$$

172 Where x is the quantity of ideal nutrients i ; y is the quantity of non-ideal nutrients j ;
 173 $Nutrient_i$ is the content of ideal nutrients i in per 100 g raw mariculture products; $Nutrient_j$ is
 174 the content of non-ideal nutrients j in per 100 g raw mariculture products; DRI_i is the daily
 175 recommended intake of ideal nutrients i ; and MRI_j is the maximum recommended daily intake of
 176 non-ideal nutrients j . Equation (9) takes the mass of mariculture products as the reference value
 177 and, by comparison, the nutritional density score is also calculated with the protein and calorie of
 178 mariculture products as the reference value:

$$179 \quad NDS-B = \sum_{i=1}^x \frac{Nutrient_i}{DRI_i} \times \frac{100}{P_i} - \sum_{j=1}^y \frac{Nutrient_j}{MRI_j} \times \frac{100}{P_i} \quad (10)$$

$$180 \quad NDS-C = \sum_{i=1}^x \frac{Nutrient_i}{DRI_i} \times \frac{100}{E_i} - \sum_{j=1}^y \frac{Nutrient_j}{MRI_j} \times \frac{100}{E_i} \quad (11)$$

181 Here, $Nutrient_i$ and $Nutrient_j$ in $NDS-B$ is the content of deal nutrients i and non-ideal
 182 nutrients j in per 100 g protein of raw mariculture products, and P_i is the protein content per 100
 183 g of raw mariculture products. In $NDS-C$, $Nutrient_i$ and $Nutrient_j$ is the content of deal
 184 nutrients i and non-ideal nutrients j in per 100 kcal of raw mariculture products, and E_i is the
 185 calorie per 100 g of raw mariculture products.

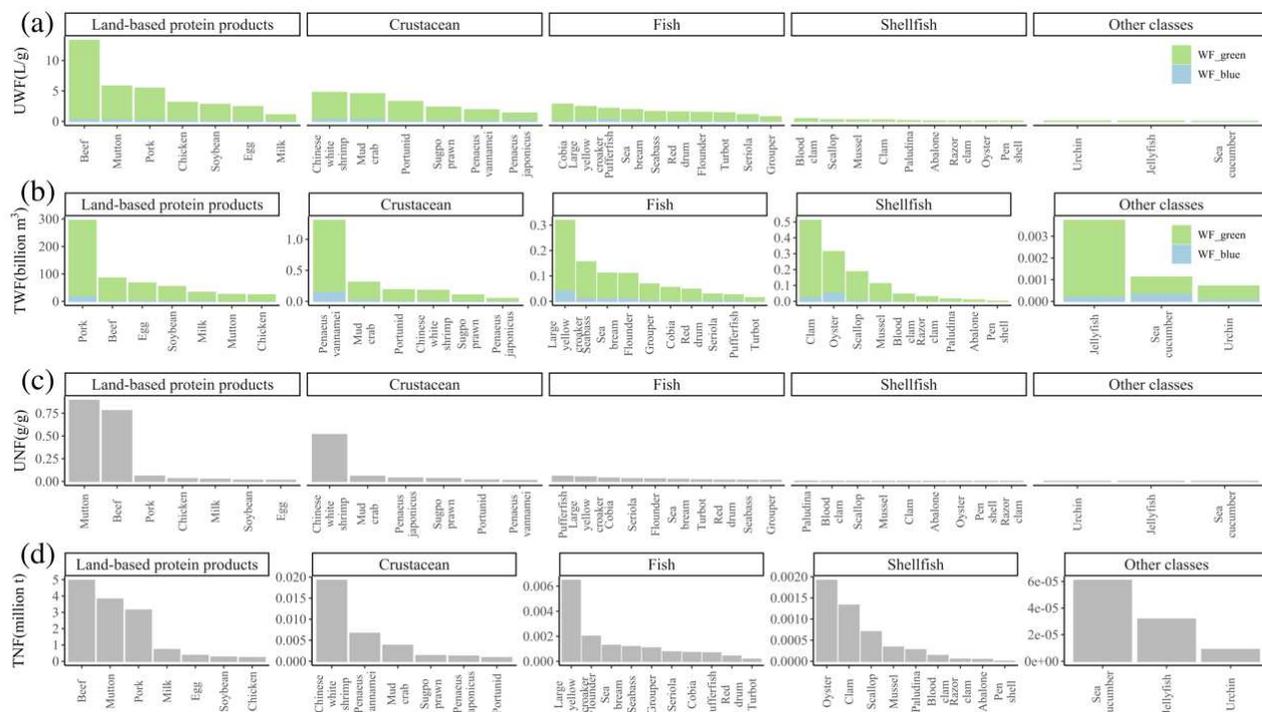

186 Nutrient content data was mainly obtained from the China Food Composition Database
187 (NINH, 2018; NINH, 2019). Nutrient content refers to the nutrient content of an uncooked
188 product, excluding inedible parts (such as bones, skin and shells). The nutritional content of the
189 mariculture product refers only to the edible portion. For LPPs, the nutritional value used was a
190 weighted average based on the nutritional content of the different parts of the animal and their
191 respective weight ratios in the total weight of the boneless carcass of the animal. A total of 22
192 nutrients were included in the nutritional assessment, amongst which sodium and saturated fatty
193 acids were classified as non-ideal, and all other nutrients were classified as ideal (Table S12).
194 Reference values (Table S13) included the recommended daily intakes (*DRI*) of ideal nutrients and
195 the maximum recommended daily intakes (*MRI*) of non-ideal nutrients (CSN, 2016; CSN, 2014).
196 The reference value was expressed for the general population aged 18 to 65 years, and the average
197 value was used for gender-specific recommended nutrients.

198 **3. Results**

199 **3.1 Water footprint and nitrogen footprint of 28 mariculture products**

200 Our results show the UWF of different mariculture products varied significantly (Fig. 1a).
201 Amongst the 28 mariculture products, Chinese white shrimp and mud crab had the highest UWF
202 (4.76 L g^{-1} and 4.56 L g^{-1} , respectively), whilst jellyfish and sea cucumber had the lowest UWF
203 (0.05 L g^{-1} and 0.01 L g^{-1} , respectively). Aggregating individual mariculture products into different
204 categories we found crustacean had the highest UWF, followed by fish, shellfish, and other classes
205 (Table S5). In comparison to LPPs, mariculture products had significantly lower UWFs. The
206 production weighted average UWF for 28 mariculture products was 0.47 L g^{-1} (SD: 0.002;
207 [95%CI: 0.40, 0.55]) (green water accounted for 89.27%, blue water accounted for 10.73%),
208 which was about one eighth of the UWF for LPPs (3.84 L g^{-1}). Such a large difference may be
209 explained by their feed ingredients and feed conversion rate, i.e. total feed divided by total species
210 group biomass increase, whereby the lower the conversion rate the higher the conversion
211 efficiency (Table S4) (Boyd et al., 2007). The feed ingredients of LPPs were mainly animals and
212 grains with high UWF, and the feed conversion rate of LPPs ranged between approximately 2.00
213 and 8.00 (Mekonnen and Hoekstra, 2012). In contrast, between around 30.00% and 60.00% of

214 mariculture products' feed ingredients came from fish meal and miscellaneous fish with UWF
 215 close to zero. The average feed conversion rate of mariculture products was also lower (1.52)
 216 compared to that of LPPs (Tables S2-S4).

217
 218 Fig. 1. Environmental indicators of mariculture products and LPPs in China in 2018. (a) UWF; (b)
 219 TWF; (c) UNF; (d) TNF. The bar charts categorize the water and nitrogen footprints of 28
 220 mariculture products (10 fish, 6 crustacean, 9 shellfish and 3 other classes) and 7 LPPs (beef,
 221 mutton, pork, chicken, milk, egg and soybean). Calculation of water footprint and nitrogen
 222 footprint refers to the corresponding index of edible parts of the product.

223 However, not all mariculture products had lower UWF than LPPs (Fig. 1a). Some products,
 224 categorized within crustacean and fish, had higher UWF than certain LPPs. For example, the UWF
 225 of crustacean including Chinese white shrimp (4.76 L g^{-1}), mud crab (4.56 L g^{-1}) and portunid crab
 226 (3.28 L g^{-1}) were higher than that of chicken (3.12 L g^{-1}), soybean (2.80 L g^{-1}), egg (2.43 L g^{-1})
 227 and milk (1.08 L g^{-1}). Cobia (2.82 L g^{-1}) and large yellow croaker (2.44 L g^{-1}) within the fish
 228 category had higher UWF than egg and milk. These mariculture products therefore had no obvious
 229 water saving advantage compared to the selected LPPs.

230 Similarly, the TWF of mariculture products was significantly lower than for LPPs in China
231 (Fig. 1b). In 2018, the TWF of the 28 mariculture products produced in China was 4.29 billion m³
232 (88.67% for green water and 11.33% for blue water), compared with 582.31 billion m³ for LPPs.
233 The TWF of different mariculture products varied significantly by category. Crustacean had the
234 largest TWF, accounting for 49.63% of the TWF of mariculture products, followed by shellfish
235 (28.44%), fish (21.80%) and other classes (0.13%) (Table S8). The large TWF of crustacean was
236 mainly due to Chinese white shrimp, which contributed 61.32% of total TWF of crustacean.

237 We observed similar results for UNF, which for mariculture products (0.01g g⁻¹) was
238 significantly less than that of LPPs (0.09 g g⁻¹) (Fig. 1c). Amongst all mariculture products and
239 LPPs, mutton had the highest UNF of 0.89 g g⁻¹ nitrogen pollution, followed by beef (0.78 g g⁻¹),
240 whilst shellfish and other mariculture classes had the lowest UNF.

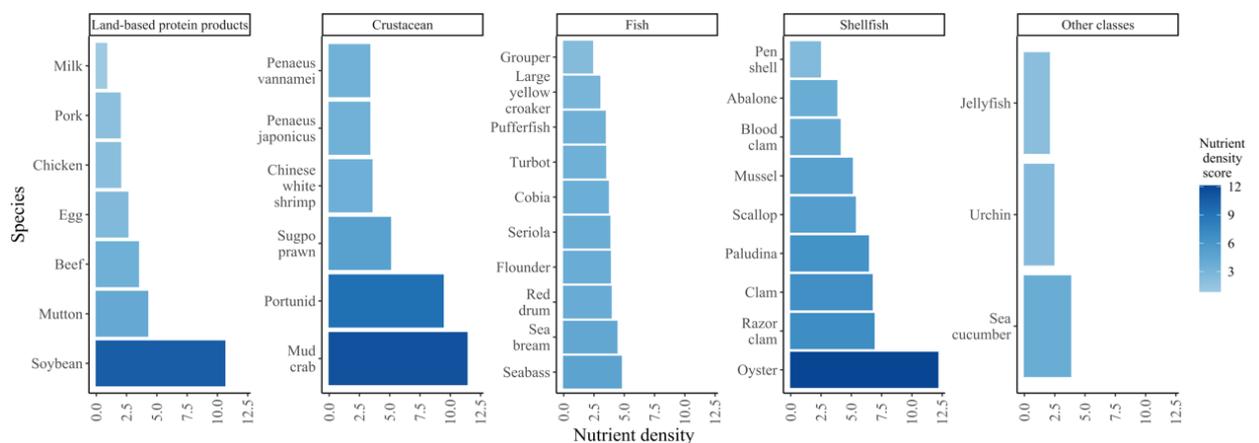

241 However, not all mariculture products had smaller UNF than LPPs. The production weighted
242 average UNF of crustacean (0.03 g g⁻¹) and fish (0.03 g g⁻¹) were higher than that of chicken
243 (0.03g g⁻¹), milk (0.02 g g⁻¹), soybean (0.01 g g⁻¹) and egg (0.01 g g⁻¹) (Tables S10-S11). The UNF
244 of Chinese white shrimp (0.52 g g⁻¹) was ranked third highest in terms of nitrogen emissions, after
245 mutton and beef. This is because the feed formulations for Chinese white shrimp contain large
246 proportions (about 40%) wheat bran and meat powder, which are higher than for other mariculture
247 products (Fig. 1c, Table S2).

248 The combined TNF of mariculture products was 0.05 million tons in 2018, largely derived
249 from Chinese white shrimp (36%). In contrast, the TNF of LPPs was much larger ranging from
250 0.23 to 4.96 million tons (Table S11). We also quantified the water and nitrogen footprints per
251 gram protein and per calorie. These results show that obtaining calories and protein from
252 mariculture products, especially non-crustacean, generally needed less water and had lower
253 nitrogen pollution than from LPPs (Figs. S1-S2, Tables S7-S8).

254 **3.2 Nutrient density of mariculture products**

255 We calculated the nutrient density score for mariculture products and LPPs using 18
256 micronutrients and 4 macronutrients. Three indicators were used, including mass (*NDS-A*), protein
257 (*NDS-B*) and calorie (*NDS-C*) (see methods). The nutrient density score of mariculture products

258 and LPPs in China using *NDS-A* is presented in the main text (Fig. 2), and *NDS-B* and *NDS-C* in
 259 the Appendix (Tables S14-S16). In general, mariculture products showed better nutritional quality
 260 properties with an average nutrient density score of 7.65, which was higher than that of LPPs
 261 (3.06). Most LPPs were ranked in the bottom half amongst all products in terms of their nutrient
 262 density (Table S16). However, there were some examples of LPPs with very high nutrient density
 263 scores. For example, the nutrient density score of soybean (10.60) was higher than most
 264 mariculture products, except oyster (12.13) and mud crab (11.37). The nutrient density score of
 265 mutton (4.24) was higher than many crustacean and fish. The nutrient density of some fish
 266 (grouper, large yellow croaker, turbot and pufferfish) was ranked in the bottom ten, with rankings
 267 close to those of chicken and pork. The lower nutritional performance of some fish may be
 268 attributed to the lower content of ideal nutrients (iron, zinc, etc), or that the content of undesired
 269 nutrients (sodium and saturated fatty acids) was higher, compared to other mariculture products
 270 (Table S12).

271

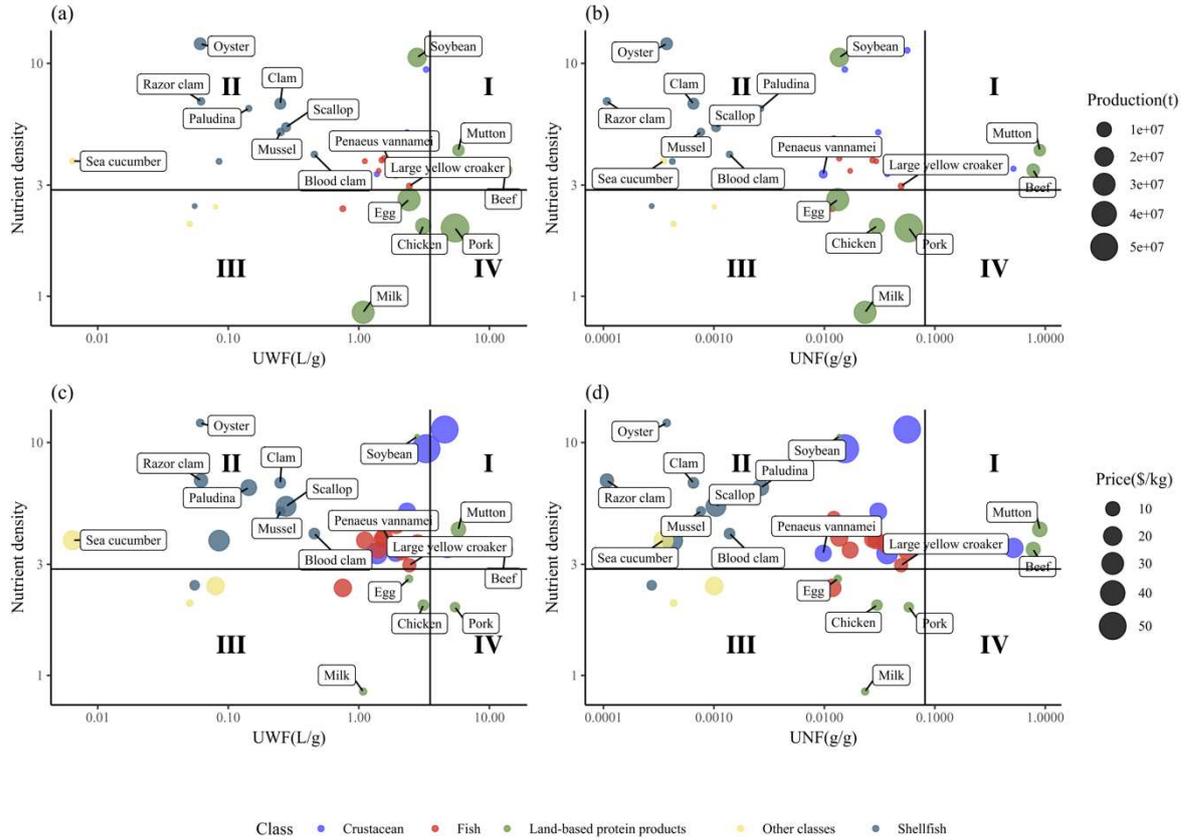

272 Fig. 2. Nutrient density scores of mariculture products and LPPs in China, based on classification
 273 and individual product. Color depth indicates the nutrient density score of various products; the
 274 darker the color, the higher the nutrient density. Calculation of nutrient density score relates to the
 275 corresponding index of the edible part of the product.

276 The high nutrient density scores of mariculture products were mainly due to their high
 277 micronutrient content (Fig.S6). However, the effects of various micronutrients on nutrient density
 278 score varied between mariculture products and LPPs (Table S18). Copper, selenium and vitamin

279 B12 were the main micronutrients contributing to the nutrient density score of mariculture
280 products, by more than 10% respectively. The nutrients contributing most to the nutrient density
281 score of land-based animal protein products were zinc, copper and vitamin B12. For land-based
282 plant protein soybean, the effects of vitamin E, copper and omega-3 on nutrient density fractions
283 were more than 10% respectively. Vitamin B12 was mainly contained in meat and seafood.

284 **3.3 Win-win and trade-off relationships between mariculture products and LPPs**

285 Combining nutrient density indicators and environmental indicators (UWF and UNF) for 28
286 mariculture products and 7 LPPs, we grouped all products into four quadrants (Fig. 3). We also
287 compared the combined nutritional and environmental impacts of different products on a protein
288 and calorific basis (Figs. S7-S8), which showed a similar pattern as in Fig. 3. Products in quadrant
289 II were both nutritionally and environmentally friendly. We found 17 out of 28 mariculture
290 products were distributed in quadrant II (Fig. 3), which was dominated by fish and shellfish.
291 Soybean was the only LPP in quadrant II. However, the production volume of products in
292 quadrant II only accounted for 19% of the total production volume of all products. LPPs were
293 mainly distributed in quadrants III and IV where the nutrient density was lower than the mean
294 value (3.49). Our results also showed LPPs had a lower price and greater production volume than
295 mariculture products (Fig. 3). Generally, mariculture products were distributed in quadrants II and
296 III, where the environmental impact was lower than the mean values (3.52 L g⁻¹ for UWF and 0.08
297 g g⁻¹ for UNF).

298

299 Fig. 3. Comparison of environmental and nutritional impacts of mariculture products and LPPs in
 300 China in 2018. Fig. a and Fig. c show the relationship between UWF and nutrient density; Fig. b
 301 and Fig. d show the relationship between UNF and nutrient density. The size of the bubbles in Fig.
 302 a and Fig. b represents the total production of each product in 2018 (FBCM, 2019; SBPR, 2019).
 303 The size of the bubbles in the Fig. c and Fig. d reflects the price of each product in 2018 (edible
 304 part only) (RSE, 2019). The color of the bubbles indicates the category of product, and the
 305 crosshair in the center is based on the weighted average of all products. Products with labels
 306 represent the top half of products by production volume. Each chart has four quadrants, namely;
 307 high nutrition and high environmental impact (quadrant I), high nutrition and low environmental
 308 impact (quadrant II), low nutrition and low environmental impact (quadrant III), and low nutrition
 309 and high environmental impact (quadrant IV).

310 Looking at the price of mariculture products and LPPs, we found the average price of
 311 mariculture products in quadrant II was relatively high. Products in quadrant III were more
 312 environmentally friendly but had less nutritional density. Overall, we found shellfish in quadrants

313 II and III had greater production volume, accounting for 84.5% of total mariculture production,
314 but had a lower average price than other mariculture product categories. Fish in quadrant III had
315 no obvious advantage in terms of environmental impact compared with egg, chicken and milk,
316 which were also cheaper.

317 Only two species in crustacean (Chinese white shrimp and mud crab), and three LPPs (beef,
318 pork and mutton) were located in quadrants I and IV, which had greater environmental impacts
319 than for other products. Pork was located in quadrant IV for UWF, but in quadrant III for UNF. In
320 contrast, mud crab was located in quadrant I for UWF, but in quadrant II for UNF. Pork had an
321 overwhelming production volume compared to other products, but a relatively lower price.

322 **4. Discussion**

323 Our findings reveal that obtaining nutrients from mariculture products as a whole was more
324 environmentally friendly than getting them from LPPs. However, different categories of
325 mariculture products varied greatly in terms of environmental impact and nutritional value. Not all
326 mariculture products are ideal substitutes for LPPs when considering environmental impact,
327 nutritional performance and price. The current structure of the mariculture industry in China may
328 be optimized by expanding the production of nutrient-rich mariculture products with low
329 environmental impact and affordable price.

330 Amongst all categories of mariculture, shellfish showed most promise in acting as a
331 substitute for LPPs. First, shellfish have greater production expansion potential than other
332 mariculture products in China. Large-scale shellfish farming in China started in the 1950s, which
333 currently accounts for greater than 85% of global production (Willer and Aldridge, 2020). The
334 case in China also demonstrates the economic viability of shellfish farming in a rapidly
335 developing country; with innovation in production technology, shellfish could meet the protein
336 requirements of nearly 1 billion people in the most vulnerable regions of the world (Willer and
337 Aldridge, 2020). Second, apart for a few shellfish (abalone and paludina) that rely on artificial bait
338 and compound feed, most shellfish do not require feed inputs, so the overall environmental
339 footprint of shellfish is small. Shellfish are rich in micronutrients, which help supplement
340 micronutrient deficiencies in China. In addition, the price of shellfish is the lowest amongst

341 mariculture products, and is becoming an affordable seafood option for consumers. Shellfish may
342 therefore be an accessible nutrient route for populations in developing countries.

343 However, it should be cautioned that there are upper limits on daily intake of shellfish (Table
344 S19). Micronutrients (copper, zinc, iron, selenium, etc.) are ideal nutrients that have a positive
345 effect on health when consumed in moderation, but may have toxic effects when the
346 recommended daily intake limits are exceeded. Taking oyster as an example, which has the
347 highest nutrient density, frequent or large-scale consumption should be avoided due to its high
348 copper content (8.13mg/100g) compared to the recommended daily intake (0.80mg/d) (Table
349 S12). Hence, shellfish such as abalone, razor clam, cockle and oyster should only amount to less
350 than 15% of daily protein intake when taking recommended nutritional limits into consideration.
351 Upper daily intake limits may therefore constrain the development these shellfish production
352 industries as a substitute for LPPs. Moreover, our results indicate a combination of mariculture
353 and LPPs should be adopted to meet the nutritional requirements of the human body, whilst
354 balancing environmental and economic requirements (He et al., 2018).

355 Fish are beneficial to human health due to their plentiful supply of micronutrients such as
356 omega-3. However, several factors potentially constrain the further development of the
357 mariculture fish industry. First of all, there is no significant advantage in price or nutrition for
358 fish. Compared to shellfish, fish have a lower nutrient density but are more expensive. Compared
359 with LPPs, the nutrient density of fish is similar to LPPs, but the price of fish is higher than LPPs.
360 Secondly we found fish, largely because of their feed, had no obvious environmental advantage
361 compared to some LPPs. Fish feed mainly consists of two elements, one is derived from land
362 (soybean meal, wheat meal, meat and bone meal, etc.) and the other is fish meal and fish oil
363 derived from wild fish. The former has a large environmental impact, whilst the latter, although
364 the UWF and UNF are close to zero, is unsustainable in terms of the nature of capture fisheries.
365 To solve this dilemma, the combined effects of fisheries reform, reducing the use of non-
366 carnivorous mariculture in feed, and innovating new feed ingredients will help limit the
367 environmental impact of mariculture feeds in the future.

368 To ensure the development of mariculture products with lower environmental impact, higher
369 nutritional density and affordable price in China, efforts should first be made to expand the
370 production base. Increased production will require significant investment and innovation in
371 mariculture infrastructure including farming facilities, transportation, cooling and processing
372 (Vanham et al., 2013). For example, the transportation and storage costs of frozen shelled products
373 are significantly lower than those of fresh shelled products. Innovative financial methods, such as
374 microfinance, will also boost the mariculture industry. In Peru, for example, a 50% corporate tax
375 cut for aquaculture companies and incentives for private investment in innovation helped the
376 shellfish industry grow sevenfold between 2003 and 2015 (Willer et al., 2021). Infrastructure
377 combined with hatcheries with growth, purification and processing functions can further increase
378 productivity.

379 Increasing consumer demand will be the driving force underpinning rapid growth of the
380 mariculture industry, which may be achieved by improving the safety, diversity, and affordability
381 of mariculture products. Establishing seafood quality certification systems and food safety testing
382 programs, and technological solutions such as solar-powered UV purification systems and regular
383 monitoring of algal bloom toxins and parasites, can enhance consumer trust in mariculture quality
384 (Mekonnen and Hoekstra, 2012). Promoting mariculture as an affordable source of protein is also
385 key to boosting consumer demand. In addition, culinary efforts should also be made in offering a
386 range of diverse, delicious and non-perishable mariculture processed products to satisfy different
387 consumer tastes.

388 As with all studies of this type there are some limitations. Full-scale footprint accounting
389 needs to include all direct and indirect resource consumption and pollution discharges along the
390 production and consumption supply chain (Zhao et al., 2019). Although a more comprehensive
391 calculation of mariculture footprints is needed, the scope of our study and data shortages
392 prevented us from doing so. The methods applied here provided a reasonable estimate of the
393 footprint related to feed, which is equivalent to the boundary of the system used to calculate the
394 footprint of LPPs. We also established a self-sufficiency and self-seclusion hypothesis, that is,
395 assuming that both feed and mariculture products are produced and consumed only in China.

396 Under this assumption, we explore how much environmental impact the production of mariculture
397 products will have on the environment. Also, whilst we've included as many important nutrients
398 in mariculture production as possible, some important ones such as vitamin B₆ and folic acid are
399 missing from our quantification of nutrient density. We further used the Monte Carlo method to
400 estimate the uncertainty of the environmental footprint (See Appendix). Furthermore, we used the
401 calculation method of nutrient density recommended by Hallstrom et al. (2019) (see Method 2.3),
402 which assigns the same weight to different nutrients. Although this method ignores the influence
403 of different nutrients to the human body, it is more suitable for comparison of nutritional status in
404 different countries and regions.

405 **5. Conclusions**

406 Here, we conducted a detailed environmental and nutritional study on 28 mariculture
407 products in China from data in 2018, and compared them with 7 LPPs to provide a detailed list of
408 product environmental footprint and nutrient density score. It is hoped such a comprehensive
409 study will help promote ecologically sensitive and efficient development of the mariculture
410 industry in China, and provide useful indicators for development in other countries throughout the
411 world. The findings facilitate targeted mariculture production policies, and help consumers make
412 food choices of mariculture products that benefit the environment and health. Our research
413 confirms China's mariculture production has environmental and nutritional advantages compared
414 to LPPs. However, the characteristics of specific mariculture products must be considered if future
415 mariculture industry development is to achieve more environmental, nutritional, and economic
416 benefits. These characteristics include previously overlooked environmental indicators, nutrient
417 content, food intake upper limits, price and production volume. Adopting the heterogeneity of
418 different products may help policy makers identify current limitations in substituting mariculture
419 products with LPPs.
