Keywords: *2D magnets, isothermal magnetic entropy change, adiabatic temperature change, specific cooling power, strain tunability*

Two-dimensional magnets could potentially revolutionize information technology, but their potential application to cooling technology and magnetocaloric effect (MCE) in a material down to the monolayer limit remain unexplored. Herein, we reveal through multiscale calculations the existence of giant MCE and its strain tunability in monolayer magnets such as CrX_3 ($X = \text{F}, \text{Cl}, \text{Br}, \text{I}$), CrAX ($A = \text{O}, \text{S}, \text{Se}; X = \text{F}, \text{Cl}, \text{Br}, \text{I}$), and Fe_3GeTe_2 . The maximum adiabatic temperature change ($\Delta T_{\text{ad}}^{\text{max}}$), maximum isothermal magnetic entropy change, and specific cooling power in monolayer CrF_3 are found as high as 11 K, $35 \mu\text{J m}^{-2} \text{K}^{-1}$, and 3.5 nW cm^{-2} under a magnetic field of 5 T, respectively. A 2% biaxial and 5% a -axis uniaxial compressive strain can remarkably increase $\Delta T_{\text{ad}}^{\text{max}}$ of CrCl_3 and CrOF by 230% and 37% (up to 15.3 and 6.0 K), respectively. It is found that large net magnetic moment per unit area favors improved MCE. These findings advocate the giant-MCE monolayer magnets, opening new opportunities for magnetic cooling at nanoscale.

1 Introduction

Two-dimensional (2D) magnets, such as $\text{Cr}_2\text{Ge}_2\text{Te}_6$, CrI_3 , VSe_2 , Fe_3GeTe_2 , VI_3 [1–6], have motivated numerous explorations of novel magnetic properties and their applications down to the monolayer limit over the past few years [7–12]. With the additional spin degree of freedom and emergent phenomena in the 2D limit, 2D magnets have shown intriguing prospects in fields such as spin valves [13], magnetic tunnel junctions [14], magnetic random access memory [15, 16], and quantum computing [17, 18]. These applications of 2D magnets favor the development of miniaturized spintronic and magnonic devices [19–22] and could potentially revolutionize the next-generation of information storage/transport technologies [23–26]. Comparatively, the application of 2D magnets in cooling technology has been relatively underdeveloped compared to the tremendous efforts put into exploiting 2D magnets for information technology. Considering the flexibility of 2D magnets and the potential for mechanical deformation, their application in cooling technology is promising.

Cooling technology by using magnetic materials is intrinsically attributed to the magnetocaloric effect (MCE). MCE is a magneto-thermodynamic phenomenon. By exposing magnets to an external magnetic field, a reversible temperature and entropy change could be achieved to result in a targeted cooling or heating. MCE in bulk magnetocaloric materials have been demonstrated to enable highly efficient and environmentally friendly solid-state cooling technology that is a promising alternative to conventional gas-compression refrigerators [27–31]. Despite this, studies on MCE in layered van der Waals (vdW) materials

are still rare. Layered vdW magnets provide a platform for studying the thickness dependent MCE, which have enormous applications in low-dimensional magnetic refrigeration.

Recently, MCE in the bulk counterparts of 2D vdW magnets have been investigated, and the figures of merit for the MCE evaluation (e.g., maximum adiabatic temperature change $\Delta T_{\text{ad}}^{\text{max}}$, maximum magnetic entropy change $-\Delta S_{\text{M}}^{\text{max}}$) are reported [32–37]. For instance, by using the heat capacity data at an out-of-plane magnetic field up to 9 T, $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ of bulk CrI_3 single crystals are estimated as 2.34 K and $5.65 \text{ J kg}^{-1} \text{ K}^{-1}$, respectively. In addition, MCE in bulk CrI_3 single crystals is found to be anisotropic [32, 37] and the mechanism of this phenomenon is clarified theoretically, which depends on the anisotropic magnetic susceptibility and magnetization anisotropy [37]. Similarly, for bulk CrBr_3 single crystals under an in-plane magnetic field of 5 T, $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ are measured as around 2.37 K and $7.2 \text{ J kg}^{-1} \text{ K}^{-1}$, respectively [33]. Later, bulk CrCl_3 are reported to have $-\Delta S_{\text{M}}^{\text{max}}$ of $14.6 \text{ J kg}^{-1} \text{ K}^{-1}$ under an in-plane magnetic field of 5 T [34]. Furthermore, a magnetic field of 7 T is shown to induce a large $\Delta T_{\text{ad}}^{\text{max}}$ of 6.2 K and $-\Delta S_{\text{M}}^{\text{max}}$ of $19 \text{ J kg}^{-1} \text{ K}^{-1}$ in bulk CrCl_3 [35]. In contrast to bulk CrI_3 [32], MCE in bulk CrCl_3 is isotropic [35]. In contrast to typical magnetocaloric materials (such as $\text{La}(\text{Fe},\text{Si})_{13}$ family, $\text{Gd}_5(\text{Si},\text{Ge})_4$ family, and rare earth compounds) [38], these vdW magnets exhibit superior magnetothermal properties and are suitable for use in low-temperature working environments up to 100 K. Additionally, MCE in magnetic films is widely examined experimentally, but the film is of a thickness around 10^1 – 10^4 nm [39–41] and is much thicker than a monolayer layer. Thus, most of the current studies are restricted to bulk and film magnets and MCE in monolayer magnets remains to be explored.

In this work, we provide the new insight on the MCE of magnets down to the monolayer limit by a multiscale theoretical approach integrating *ab-initio* calculations, atomistic spin simulations, and magnetocaloric thermodynamics. Specifically, monolayer magnets such as CrX_3 ($X = \text{F}, \text{Cl}, \text{Br}, \text{I}$) and CrAX ($A = \text{O}, \text{S}, \text{Se}; X = \text{F}, \text{Cl}, \text{Br}, \text{I}$) are taken as model systems to explore their MCE. By using the magnetic parameters from *ab-initio* calculations, atomistic spin model simulations are performed to determine the temperature dependent demagnetization curves, from which MCE is evaluated via the Maxwell relations. It is found that MCE indeed remains in these 2D magnets and can be remarkably tuned by strain. More importantly, giant MCE with a $\Delta T_{\text{ad}}^{\text{max}}$ around 15.3 K is realized in magnets down to the monolayer limit. These results provide theoretical guidance to probe MCE in 2D magnets, and could promote 2D magnets toward applications for cooling or thermal management in compact and miniaturized nanodevices.

2 Results And Discussion

2.1 Strain-tunable magnetic properties

CrX_3 exhibits a rhombohedral lattice (space group $R\bar{3}$), while the atomic arrangement of CrAX shows an orthorhombic structure (space group $Pm\bar{m}n$). The top and side views of CrX_3 and CrAX structures are shown in Fig 1, in which the associated primitive cells are highlighted with red lines. The optimized lattice parameters are summarized in Table 1, agreeing well with the previous works [42–45]. Exfoliation experiments of CrI_3 [2], CrBr_3 [46], CrOCl [47], CrOBr [48], and CrSBr [48] have been carried out to show that the intrinsic ferromagnetism can maintain from the bulk to few-layer or even monolayer thickness. In addition, for certain CrX_3 and CrAX which are not experimentally synthesized yet, their dynamic stability and existence possibility have been confirmed by a suite of theoretical studies [42, 49–51]. The calculated phonon dispersion spectra of CrAX are shown in Fig. S1 (supporting information), proving the dynamic stability of these monolayers.

The magnetic parameters of monolayer CrX_3 and CrAX are recorded in Table 1. Magnetism in these chromium-containing compounds originates from the incompletely filled electrons in d orbitals of Cr ions. The net magnetic moment per primitive cell (M_{tot}) is about $6 \mu_{\text{B}}$, whereas the magnetic moment of Cr

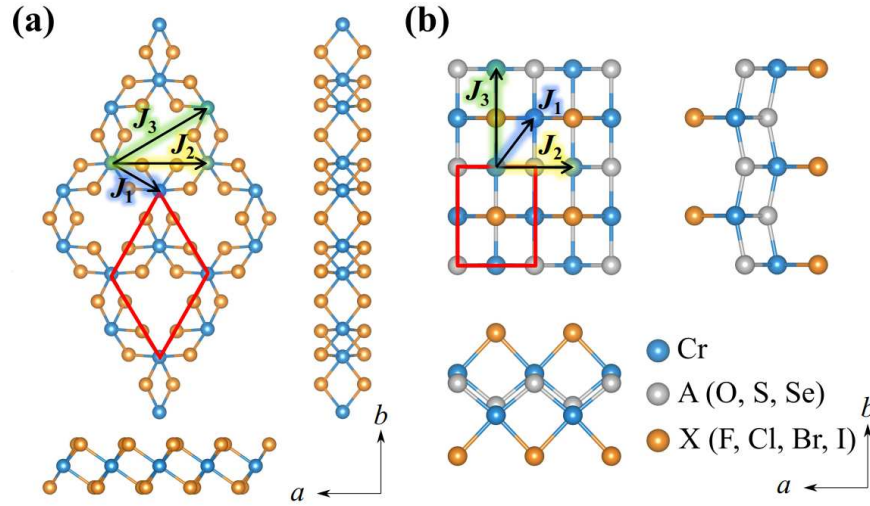

Figure 1: Crystal structures of (a) CrX_3 and (b) CrAX monolayers from the top and side views. The c axis is perpendicular to the plane composed of a axis and b axis.

atoms (M_{Cr}) is clearly different in these monolayers. Magnetocrystalline anisotropy energy (MAE) the associated easy/hard axis directions are also summarized in Table 1. The monolayers with iodine atoms show strong magnetocrystalline anisotropy. For instance, CrI_3 , CrSI , and CrSeI possess a large out-of-plane MAE of 0.745, 1.022, and 0.921 meV, respectively, owing to the strong spin-orbit coupling (SOC) in iodine atoms. The out-of-plane energy of CrF_3 , CrCl_3 , CrBr_3 , CrI_3 , CrOF , CrOCl , and CrSeI is lower than the in-plane one, so an easy axis parallels to c direction holds. Similarly, the easy axis of CrSeCl and CrSeBr is along the a axis. Specially, since the energy in the y direction is larger than that in other directions for

Table 1: Magnetic properties and magnetocaloric parameters including optimized lattice constants (a and b , Å), net magnetic moment per primitive cell (M_{tot} , μ_B), magnetic moment per Cr atom (M_{Cr} , μ_B), net magnetic moment per unit area (\bar{M}_{tot} , μA), easy or hard axis direction, magnetocrystalline anisotropy energy (MAE, meV/Cr), the nearest (J_1 , meV), next-nearest (J_2 , meV), and third-nearest (J_3 , meV) neighboring exchange interactions, Curie temperature (T_c , K), maximum magnetic entropy change at 5 T ($-\Delta S_{\text{M}}^{\text{max}}$, $\mu\text{J m}^{-2} \text{K}^{-1}$) and maximum adiabatic temperature change at 5 T ($\Delta T_{\text{ad}}^{\text{max}}$, K) for the 13 monolayers.

CrOBr, CrSCl, CrSBr, and CrSI, the b axis is regarded as the hard axis.

The exchange interaction parameters are also listed in Table 1. The positive values of exchange parameters J_1 and J_2 reflect the ferromagnetic coupling in monolayers. J_1 is increased by 2.73 meV in CrX₃ with X varying from F to I, suggesting an enhancement in ferromagnetic coupling. Besides, J_1 and J_2 are one order of magnitude larger than J_3 in CrX₃, and are expected to dominate T_c and the demagnetization behaviors. In contrast, for CrOX, J_3 is even larger than J_1 and J_2 . This is possibly attributed to the different atomic structures for forming J_2 and J_3 [52]. J_3 is formed by the super-exchange paths between two neighbor Cr atoms intermediated by an oxygen atom, i.e., Cr–O–Cr in 180°. Whereas, J_2 is formed by two interactions Cr–O–Cr and Cr–X–Cr in 90° [53,54]. Replacement of Cl with Br or I slightly changes J_1 and substantially enlarges J_2 and J_3 in CrSX and CrSeX.

The influence of strain on magnetic properties are further examined. Biaxial strain is applied to CrX₃ and the results are depicted in Fig. 2. The biaxial tensile strain slightly enhances M_{Cr} , but considerably increases the lattice area. Thus the slight increase of M_{Cr} is canceled out and the net magnetic moment per unit area (\bar{M}_{tot}) is decreased, as seen in Fig. 2a. MAE of CrI₃ decreases with biaxial strain, while MAE of CrBr₃, CrCl₃, and CrF₃ increases with it, as shown in Fig. 2b. The impact of strain on exchange parameters J_1 and J_2 is demonstrated in Fig. 2c and 2d, respectively. It is found that J_1 of CrX₃ is reduced by applying biaxial strain in spite of the tensile or compressive types. J_1 of CrBr₃, CrCl₃, and CrF₃ under -5% compressive biaxial strain becomes negative, confirming that the modulation from ferromagnetic to antiferromagnetic coupling can be realized by applying compressive biaxial strain. J_2 of CrF₃ and others (CrI₃, CrBr₃, CrCl₃) increases and decreases with the biaxial strain, respectively. The effect of tensile

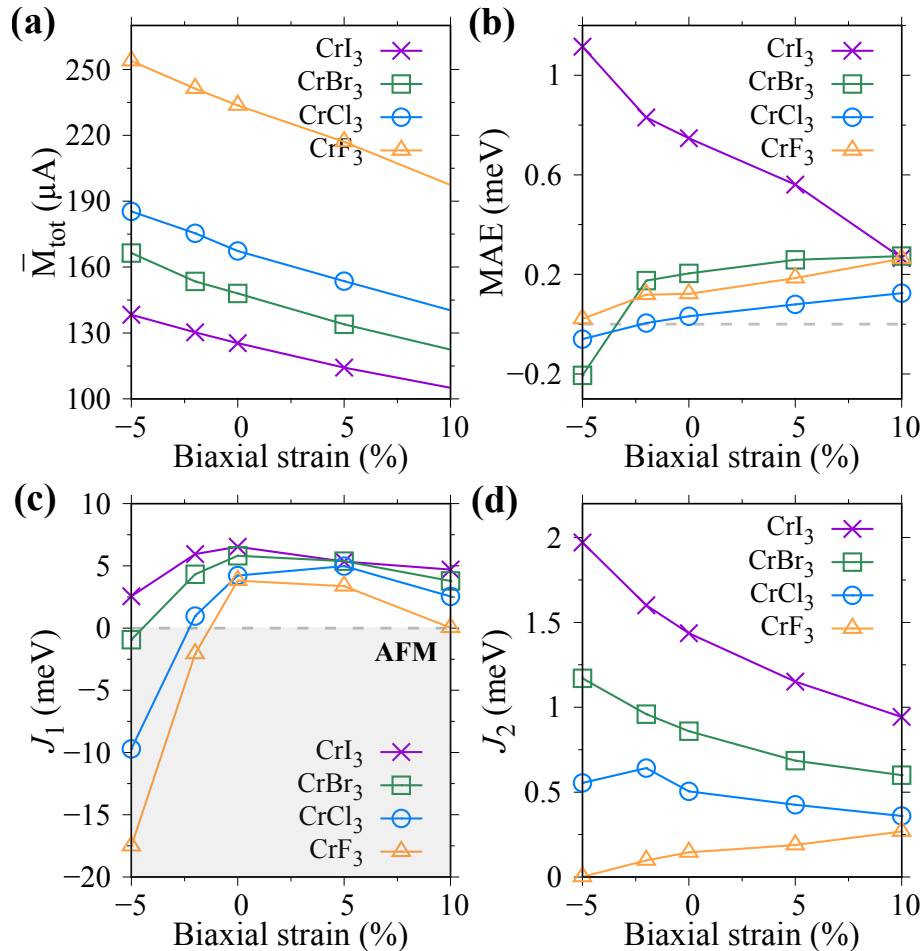

Figure 2: Strain-tunable magnetic properties of CrX₃: (a) net magnetic moment per unit area, (b) MAE, and exchange parameters (c) J_1 and (d) J_2 .

and compressive uniaxial strains in CrAX is also investigated and the results are summarized in Figs. S2 and S3. In addition, it is stated that [55,56] exchange parameters could be affected by finite temperature induced atom displacements. However, as shown in Fig. S4, for 2D magnets whose MCE works at low temperatures, atom displacements are too small to notably affect magnetic properties, indicating the reasonable approximation of applying zero-K magnetic parameters in the classic spin Hamiltonians and the inconspicuous finite-temperature effect on MCE at low temperatures. Nevertheless, further in-depth studies are essential to calculate magnetic properties by considering atom displacements from vibration modes of 2D magnets if elevated temperatures are of interests.

2.2 Demagnetization behavior at finite temperatures

The typical isothermal magnetization curves for CrI₃ and CrOBr at different temperatures are shown in Fig. 3. A striking distinction of saturation magnetization between CrI₃ and CrOBr can be noticed in Fig. 3a and 3b. For CrX₃ and CrAX with similar net magnetic moment, the monolayer with smaller lattice area possesses larger \bar{M}_{tot} and thus higher saturation magnetization at the same temperature. The magnetization curves of other monolayers are shown in Figs. S5–S8.

Figure 3 also indicates the anisotropy of the magnetization curve with respect to the direction of the applied magnetic fields, but the anisotropy is un conspicuous at elevated temperatures. Owing to the hexagonal structures of CrX₃, the demagnetization behavior is almost identical when the magnetic field is applied along *a* or *b* axis. The magnetization curves of CrI₃ are hard to saturate under an in-plane magnetic field, while they reach saturation easily under an out-of-plane one, as shown in Fig. 3a. This indicates *c* as the easy axis at finite temperatures, agreeing with the high out-of-plane MAE of CrI₃ in Table 1. In contrast, as shown in Fig. 3b, CrOBr presents different magnetization curves in all the three crystallographic axes, owing to its in-plane tetragonal structure. Our density functional theory (DFT) calculation with SOC predicts the highest energy with magnetization along *b* axis (E_b) and thus *b* as the hardest axis (i.e. $E_b > E_c > E_a$). However, Fig. 3b indicates that magnetization along *c* axis is even much harder to be demagnetized than that along *b* axis. This disagreement arises from the competition between the demagnetization energy in the atomistic spin model and the intrinsic MAE from DFT calculations. The minimization of demagnetization energy favors the in-plane alignment of magnetization, thus reducing E_b by 0.201 meV. Since E_b is only slightly larger than E_c ($E_b - E_c \sim 0.193$ meV), this energy reduction is enough to make E_c exceed E_b and thus *c* as the harder axis.

Similar results are also summarized in Figs. S5–S8 for other monolayers. The hard or easy axis determined by atomistic spin model simulations could differ from that by the DFT calculations. In addition to CrOBr, this phenomena exist as well in CrCl₃, CrOF, CrOCl, CrSCl, and CrSBr. The distinction is mainly attributed to the demagnetization energy. Our atomistic spin model includes the demagnetization

Figure 3: Isothermal magnetization curves of (a) CrI₃ with field up to 8 T and (b) CrOBr with field up to 5 T applied in different directions. The magnetization (M) under different magnetic fields is defined as the net magnetic moment per unit area. The curves are displayed every 10 K.

field and thus the so-called extrinsic shape anisotropy, whereas DFT calculations only give the intrinsic MAE originated from SOC.

2.3 Magnetocaloric effect and its strain tunability

First, we calculate the MCE of bulk CrI_3 and the results are shown in Fig. S9. The calculated results match the experimental measurements [32] very well, confirming the reliability of the MCE calculation methodology that integrates *ab-initio* calculations, Monte-Carlo simulations and magnetocaloric thermodynamics. Moreover, by evaluating MCE in monolayer Fe_3GeTe_2 from the experimental data [4], we find the consistence between experimental results and our theoretical predictions, as well as the indirect experimental evidence for the survive of MCE in monolayer Fe_3GeTe_2 , as shown in Fig. S10. The magnetocaloric parameters of monolayers including $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ under a magnetic field of 5 T are summarized in Table 1. It is found that CrF_3 outperforms other monolayers, with $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ exceeding 10 K and $35 \mu\text{J m}^{-2} \text{K}^{-1}$, respectively. The large $-\Delta S_{\text{M}}^{\text{max}}$ of CrF_3 is ascribed to the huge change of magnetization around T_{C} , as seen in Fig. S5a. The outstanding $\Delta T_{\text{ad}}^{\text{max}}$ of CrF_3 is determined by the smallest density and lowest specific heat capacity at low temperatures. In addition, CrOF and CrOCl also exhibit excellent MCE with $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ as high as 4 K and $31 \mu\text{J m}^{-2} \text{K}^{-1}$, respectively. Since CrOF and CrOCl possess significantly large \bar{M}_{tot} and relatively low T_{C} , their magnetization is more sensitive to the temperature change, thus boosting the $-\Delta S_{\text{M}}$ according to Equation. 2. Besides, CrSX and CrSeX have a

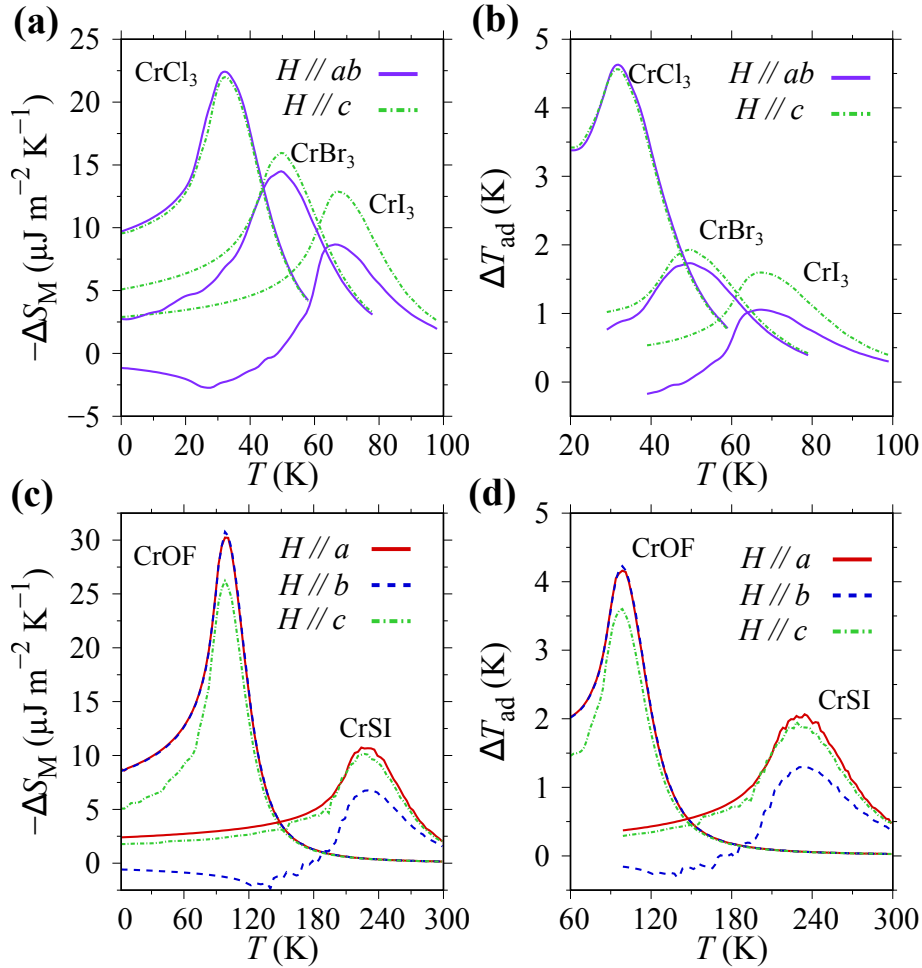

Figure 4: Temperature dependence of negative isothermal magnetic entropy change ($-\Delta S_{\text{M}}$) and the adiabatic temperature change (ΔT_{ad}) under a magnetic field of 5 T applied in different directions. (a), (b) Temperature dependence of $-\Delta S_{\text{M}}$ and ΔT_{ad} for CrCl_3 , CrBr_3 , and CrI_3 . (c), (d) Temperature dependence of $-\Delta S_{\text{M}}$ and ΔT_{ad} for CrOF and CrSI .

high $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ around 4 K and $12 \mu\text{J m}^{-2} \text{K}^{-1}$, respectively. Their T_{C} between 100–200 K makes them potentially applicable in magnetic refrigerants at medium temperatures.

The temperature dependence of $-\Delta S_{\text{M}}$ and ΔT_{ad} under a magnetic field of 5 T applied in different directions is shown in Fig. 4. $-\Delta S_{\text{M}}$ and ΔT_{ad} firstly increase with temperature and then reach their maximum around T_{C} . This maximum also increases with the applied magnetic field, as shown in Figs. S11–S17. Regardless of the directions of the applied magnetic fields at a fixed temperature, CrCl_3 exhibits an almost identical $-\Delta S_{\text{M}}$ and ΔT_{ad} , as shown in Fig. 4a and 4b. This indicates that MCE of CrCl_3 is weakly direction dependent, agreeing with the experimental observations on the bulk counterparts [34]. The isotropic MCE behavior could be ascribed to the quite low MAE of CrCl_3 in Table 1. In addition, CrOF shows isotropic in-plane MCE that is stronger than the out-of-plane one (Fig. 4c and 4d). The stronger in-plane MCE is mainly owing to the much larger demagnetization energy induced by the highest \bar{M}_{tot} of CrOF and thus much easier rotation of magnetization towards the ab plane. On the contrary, due to its large out-of-plane MAE, CrI_3 shows apparently anisotropic MCE. Specifically, $-\Delta S_{\text{M}}^{\text{max}}$ and $\Delta T_{\text{ad}}^{\text{max}}$ at 5 T reach $12.98 \mu\text{J m}^{-2} \text{K}^{-1}$ and 1.63 K along the c axis, which are 33% and 35% larger than that in the ab plane, respectively. Furthermore, there exists negative ab -plane MCE for CrI_3 at low temperatures. This is originated from the competition between the temperature dependence of magnetocrystalline anisotropy and magnetization [32]. For CrI_3 at low temperatures, as the temperature increases, the out-of-plane MAE decreases much more rapidly than the magnetization, leading to a larger in-plane magnetization

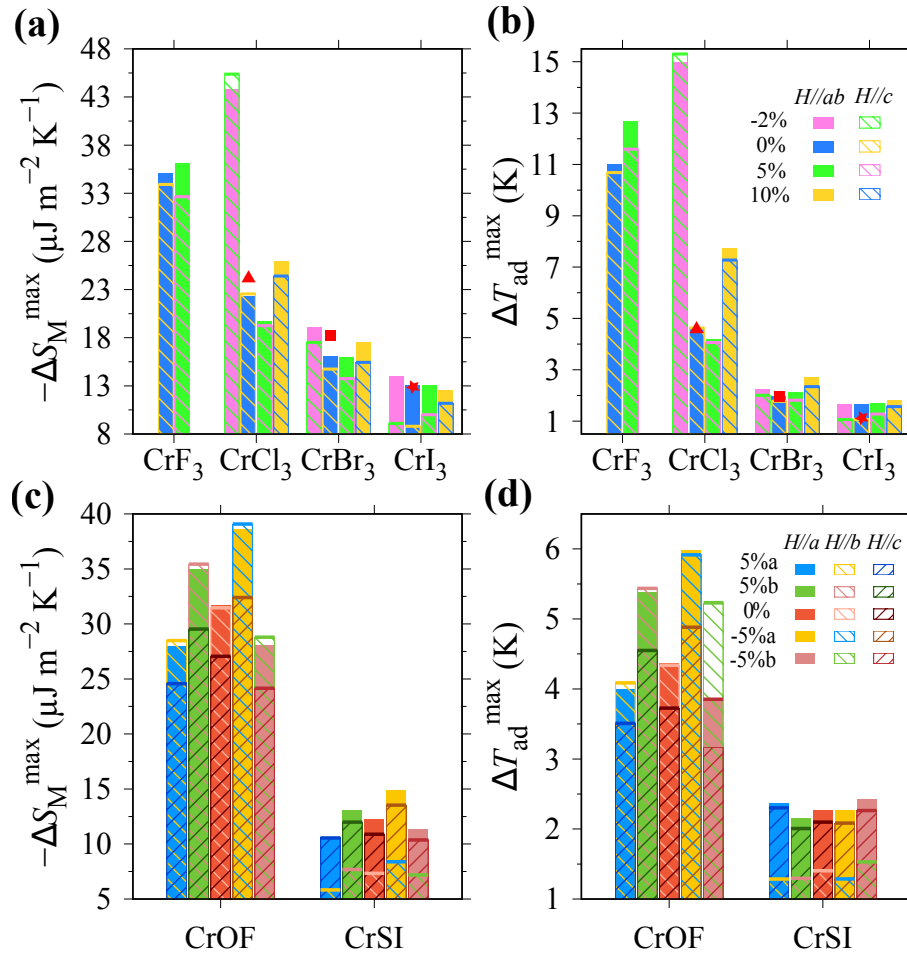

Figure 5: Strain-tunable MCE under a magnetic field of 5 T applied in different directions. (a), (b) $-\Delta S_{\text{M}}^{\text{max}}$ and $\Delta T_{\text{ad}}^{\text{max}}$ at -2% , 0% , 5% , and 10% biaxial strain for CrX_3 . (c), (d) $-\Delta S_{\text{M}}^{\text{max}}$ and $\Delta T_{\text{ad}}^{\text{max}}$ at 5% a/b -axis tensile and compressive uniaxial strain for CrOF and CrSI . The experimental data of single crystal of bulk CrCl_3 [35], CrBr_3 [33] and CrI_3 [32] is symbolized by red triangles, squares, and pentagams, respectively.

(Fig. 3). These explanations are also applicable to CrSI (Fig. 4c and 4d). $-\Delta S_M^{\max}$ and $\Delta T_{\text{ad}}^{\max}$ of these 13 monolayers as a function of magnetic field ranging from 1 to 5 T are summarized in Fig. S18.

To explore the effects of strain on MCE of monolayers, $-\Delta S_M^{\max}$ and $\Delta T_{\text{ad}}^{\max}$ with a magnetic field of 5 T under different strains are shown in Fig. 5. MCE is confirmed to weaken with decreasing layer thickness [40], while ignoring defects and vacancies of monolayers in our calculation allows for the evaluation of ideal magnetocaloric performance. It can be seen from Fig. 5a and 5b that MCE in monolayers of CrX_3 ($X = \text{Cl}, \text{Br}, \text{I}$) matches well with that in the single-crystal bulk counterparts [32, 33, 35], confirming that MCE can survive in the monolayer limit. It is also found that a considerable enhancement in MCE of CrCl_3 is realized by a -2% biaxial compressive strain, with $\Delta T_{\text{ad}}^{\max}$ and $-\Delta S_M^{\max}$ increased by 229% and 101%, respectively (Fig. 5a and 5b). This strain-induced enhancement is primarily a result of increasing \bar{M}_{tot} and decreasing T_C by the biaxial compressive strain. For MCE in CrOF, a 5% a -axis uniaxial compressive strain is revealed to induce the similar improvements in Fig. 5c and 5d, with $\Delta T_{\text{ad}}^{\max}$ and $-\Delta S_M^{\max}$ of CrOF enhanced by 36.9% and 23.3%, respectively. Although the b -axis uniaxial tensile strain reduces T_C as well, the decreased \bar{M}_{tot} prevents the significant improvement of MCE.

Since 2D MCE is evaluated in terms of per area rather than per mass or volume, it should be converted to per kilogram before being compared to MCE of typical bulk materials. 1 kg monolayer magnet corresponds to an area in the order of 10^6 m^2 that is unattainable in reality. Here, we take an ideal assumption that 2D magnets could be infinitely large, so the comparison between 2D and bulk is only theoretically feasible. Based on this theoretical and ideal consideration, $-\Delta S_M^{\max}$ and $\Delta T_{\text{ad}}^{\max}$ of monolayers and bulk magnetocaloric materials are compared in Fig. 6. The comparison between the monolayers and classical bulk MCE materials (e.g. conventional 1st and 2nd order materials, inverse 1st order materials) under a low magnetic field of 1 and 2 T [65] is presented in Fig. S19. It can be found from Fig. 6 that in terms of $-\Delta S_M^{\max}$ and $\Delta T_{\text{ad}}^{\max}$, MCE of monolayers is theoretically comparable to that of the bulk materials including typical rare-earth compounds [38, 57, 58], perovskites [59–63], and $\text{La}(\text{Fe},\text{Si})_{13}$ [28, 38, 64]. We find that monolayer CrF_3 could work around 20–30 K, which is close to the hydrogen liquefaction temperature. For the state of art of MCE in this temperature range, it is reported that bulk HoB_2 exhibits giant MCE with $-\Delta S_M^{\max}$

Figure 6: The theoretical and ideal comparison of (a) $-\Delta S_M^{\max}$ and (b) $\Delta T_{\text{ad}}^{\max}$ between the monolayers and classical bulk magnetocaloric materials (i.e., rare earth compounds [38, 57, 58], perovskites [59–63], and $\text{La}(\text{Fe},\text{Si})_{13}$ [28, 38, 64] at 5 T). CrX_3 , CrOX , CrSX , CrSeX and Fe_3GeTe_2 are represented by circles, triangles, rhombuses, pentagons, and pentagrams, respectively. Monolayers containing F, Cl, Br, and I atoms are filled with orange, blue, green, and purple, respectively. The results with strain applied to CrF_3 , CrCl_3 , CrBr_3 , CrOF , and CrSI are symbolized by smaller points. The experimental and calculated MCE of Fe_3GeTe_2 is from Fig. S10 [4].

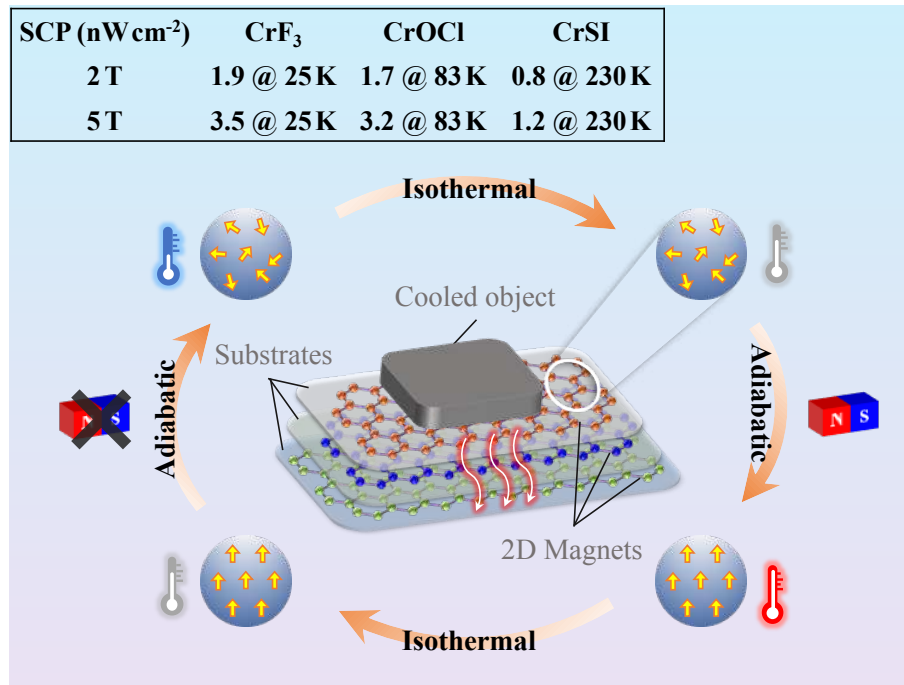

Figure 7: Schematic of refrigeration cycle using MCE of 2D magnets. SCP: specific cooling power.

$\sim 40.1 \text{ J kg}^{-1} \text{ K}^{-1}$ and $\Delta T_{\text{ad}}^{\text{max}} \sim 12 \text{ K}$ for a field change of 5 T [66]. Therefore, it can be found from Fig. 6 that MCE of monolayer CrF_3 ($-\Delta S_{\text{M}}^{\text{max}} \sim 25 \text{ J kg}^{-1} \text{ K}^{-1}$, $\Delta T_{\text{ad}}^{\text{max}} \sim 11 \text{ K}$ under 5 T) is comparable to that of bulk HoB_2 and rare-earth compounds near the liquid-hydrogen temperature. Perovskites have the advantages of low price, good chemical stability, and widely tunable transition temperature [63,67], while their MCE are unremarkable. The La-Fe-Si compounds with the first-order transition present the large entropy change near room temperature [28,63], but they suffer from lattice expansion and magnetic thermal hysteresis induced by the first-order transition. In contrast, herein the 2D magnets not only possess giant MCE that is originated from the second-order phase transition without magnetic thermal hysteresis, but also are sufficiently flexible and deformable [68] to allow the further tuning of MCE in 2D magnets by applying large strain. Therefore, mechanically robust 2D magnets could be promising candidates for the cooling of micro/nano devices.

As an illustration, Fig. 7 depicts the possibly magnetic cooling enabled by 2D magnets. As a theoretical and ideal consideration, heat is assumed to be perfectly transferred outward from the cooled object when it contacts 2D magnets under an applied periodic magnetic field. For instance, using 2D CrF_3 as MCE material with an operation frequency of 1 Hz, the ideal specific cooling power (SCP) around 25 K is close to 1.9 nW cm^{-2} at 2 T and 3.5 nW cm^{-2} at 5 T. Under the same condition, the SCP of CrSI around 230 K is 0.8 nW cm^{-2} at 2 T and 1.2 nW cm^{-2} at 5 T. The sequential stacking of 2D magnets with different working temperature windows could provide a cascade refrigeration cycle.

3 Conclusion

In summary, we confirm the survival of giant MCE and its strain tunability of magnets down to the monolayer limit including CrX_3 ($X = \text{F, Cl, Br, I}$) and CrAX ($A = \text{O, S, Se}$; $X = \text{F, Cl, Br, I}$) by multiscale simulations. It is found that CrF_3 exhibit excellent magnetocaloric performance at low temperatures owing to the smallest density and lowest specific heat capacity, with $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ up to 11 K and $35 \mu\text{J m}^{-2} \text{ K}^{-1}$ under a magnetic field of 5 T, respectively. Meanwhile, CrOF and CrOCl exhibit excellent MCE at medium temperatures with $\Delta T_{\text{ad}}^{\text{max}}$ and $-\Delta S_{\text{M}}^{\text{max}}$ as high as 4 K and $31 \mu\text{J m}^{-2} \text{ K}^{-1}$,

respectively. MCE of CrX_3 ($X = \text{F}, \text{Cl}$), CrAX ($\text{CrOF}, \text{CrOCl}, \text{CrSCl}, \text{CrSBr}$), and CrSeX is isotropic, in-plane isotropic, and anisotropic, respectively. In addition, compressive strain could effectively enhance MCE by increasing \bar{M}_{tot} and decreasing T_{C} . Particularly, a 2% biaxial and 5% a -axis uniaxial compressive strain can significantly increase $\Delta T_{\text{ad}}^{\text{max}}$ of CrCl_3 and CrOF to 15.3 and 6.0 K, respectively. Overall, these findings in our work extend the MCE research to the monolayer limit. Here, we reveal the consistency between experimental and calculated MCE for monolayer Fe_3GeTe_2 , as well as focus on the theoretical prediction of MCE and the associated mechanism in 2D magnets. The direct measurement of MCE in 2D magnets is currently challenging, but will be feasible as the measuring techniques are advanced. Monolayer magnets with giant and strain-tunable MCE could enable their applications in the cooling of micro/nanoscale space and devices.

4 Experimental Section

DFT Calculations: DFT calculations are performed using *Vienna ab initio simulation package* (VASP) [69,70] within the projector-augmented wave (PAW) method [71,72]. Exchange-correlation functional adopts Perdew-Burke-Ernzerhof (PBE) type [73] in generalized gradient approximation (GGA). Considering that the calculated results of monolayer CrI_3 without U are more consistent with the experimental values of bulk CrI_3 [74], $U = 0$ eV for CrX_3 is adopted [42]. The calculated magnetic properties of monolayer CrOCl and CrOBr with $U = 7$ eV for Cr are in better agreement with those in their bulk counterparts [45]. The magnetic moment and Curie temperature of monolayer CrSBr calculated with $U = 3$ eV agree well with the experimental measurement [75–77]. As a result, $U = 7$ eV for CrOX and $U = 3$ eV for CrSX and CrSeX are employed. A 15-Å-thick vacuum layer is set to prevent interaction between the periodic lattices along c axis. The plane-wave cutoff energy is set to 500 eV and the energy convergence criterion is 10^{-6} eV. The magnetic moment and MAE are evaluated in a primitive cell with a k -mesh of $15 \times 15 \times 1$ and $27 \times 21 \times 1$ generated by the Monkhorst-Pack scheme for CrX_3 and CrAX , respectively [78]. MAE is calculated by the difference of total energies with the spin quantization axis aligned along different crystallographic axes. In detail, noncollinear non-self-consistent calculations with SOC are carried out by reading the converged charge densities from the spin-polarized self-consistent calculations. The phonon calculations are performed by the finite displacement method in a $3 \times 3 \times 1$ supercell [79–81].

In order to calculate the temperature dependent demagnetization curves of 2D magnets, we utilize the atomistic spin model that is based on the classic spin Hamiltonian [82], i.e.,

$$\begin{aligned}
 H = E_0 - \frac{1}{2}J_1 \sum_N \mathbf{s}_i \cdot \mathbf{s}_j - \frac{1}{2}J_2 \sum_{NN} \mathbf{s}_i \cdot \mathbf{s}_j - \frac{1}{2}J_3 \sum_{NNN} \mathbf{s}_i \cdot \mathbf{s}_j \\
 - k_i \sum_i (\mathbf{s}_i \cdot \mathbf{e}_i)^2 - \sum_i \mu_s \mathbf{s}_i \cdot (\mathbf{H}_{\text{app}} + \mathbf{H}_{\text{dp}}),
 \end{aligned} \tag{1}$$

in which E_0 is the energy without spin contribution, \mathbf{s}_i the unit vector representing the atomistic spin direction at atom i , k_i the magnetocrystalline anisotropy energy of atom i , and \mathbf{e}_i the easy axis vector. μ_s is the magnetic moment of atom i . \mathbf{H}_{app} and \mathbf{H}_{dp} are the external and dipole magnetic fields, respectively. J_1 , J_2 , and J_3 are the nearest-neighbour (NN), next-NN, and third-NN exchange interaction parameters, respectively. These exchange parameters are derived by solving equations based on total energies of ferromagnetic and different antiferromagnetic configurations.

Atomistic Spin Simulations: After the parameters in Equation. 1 have been obtained from *ab-initio* calculations, the parameterized atomistic spin model is used to perform simulations by using VAMPIRE [83]. The Monte Carlo method is adopted to acquire T_{C} . After executing 10,000 steps at each temperature, the system of $50 \times 50 \times 1$ unit cells with in-plane periodic boundary conditions reaches equilibrium. Then a

statistical average is taken over by further 10,000 steps to extract the mean magnetization. The temperature dependent magnetization curves are calculated by using the spin dynamics approach and the Heun integration scheme. The demagnetization field induced by the atomistic spins themselves is also included. The external magnetic field is gradually increased to 8 T with a incremental step of 0.02 T.

Magnetocaloric Thermodynamics: The figures of merit for MCE are related to thermodynamics. The ΔS_M can be calculated from the Maxwell relation [84, 85], i.e.,

$$\Delta S_M = \int_0^H \left(\frac{\partial S}{\partial H} \right)_T dH = \mu_0 \int_0^H \left(\frac{\partial M}{\partial T} \right)_H dH, \quad (2)$$

where S is entropy, M is magnetization, and μ_0 is vacuum permeability. The degree of disorder in the magnetic moment distribution decreases as the magnetic field increases. So ΔS_M turns to a negative value. Thus, usually $-\Delta S_M$ is taken as one of the features to measure MCE. Similarly, ΔT_{ad} could demonstrate MCE directly, which can be represented as

$$\Delta T_{ad} = -\mu_0 \int_0^H \frac{T}{\rho c_p} \left(\frac{\partial S}{\partial H} \right)_T dH = -\mu_0 \int_0^H \frac{T}{\rho c_p} \left(\frac{\partial M}{\partial T} \right)_H dH, \quad (3)$$

where ρ is the density, and c_p is the specific heat capacity which is acquired by phonon calculations.

The existence of giant magnetocaloric effect (MCE) and its strain tunability in monolayer magnets such as CrX_3 ($X = F, Cl, Br, I$), $CrAX$ ($A = O, S, Se; X = F, Cl, Br, I$), and Fe_3GeTe_2 are revealed through multiscale calculations. MCE of 2D magnets is theoretically comparable to that of bulk materials and can be remarkably tuned by strain. In particular, CrF_3 possesses the state-of-the-art MCE at low temperatures. These findings advocate the giant-MCE monolayer magnets, opening new opportunities for magnetic cooling at nanoscale.

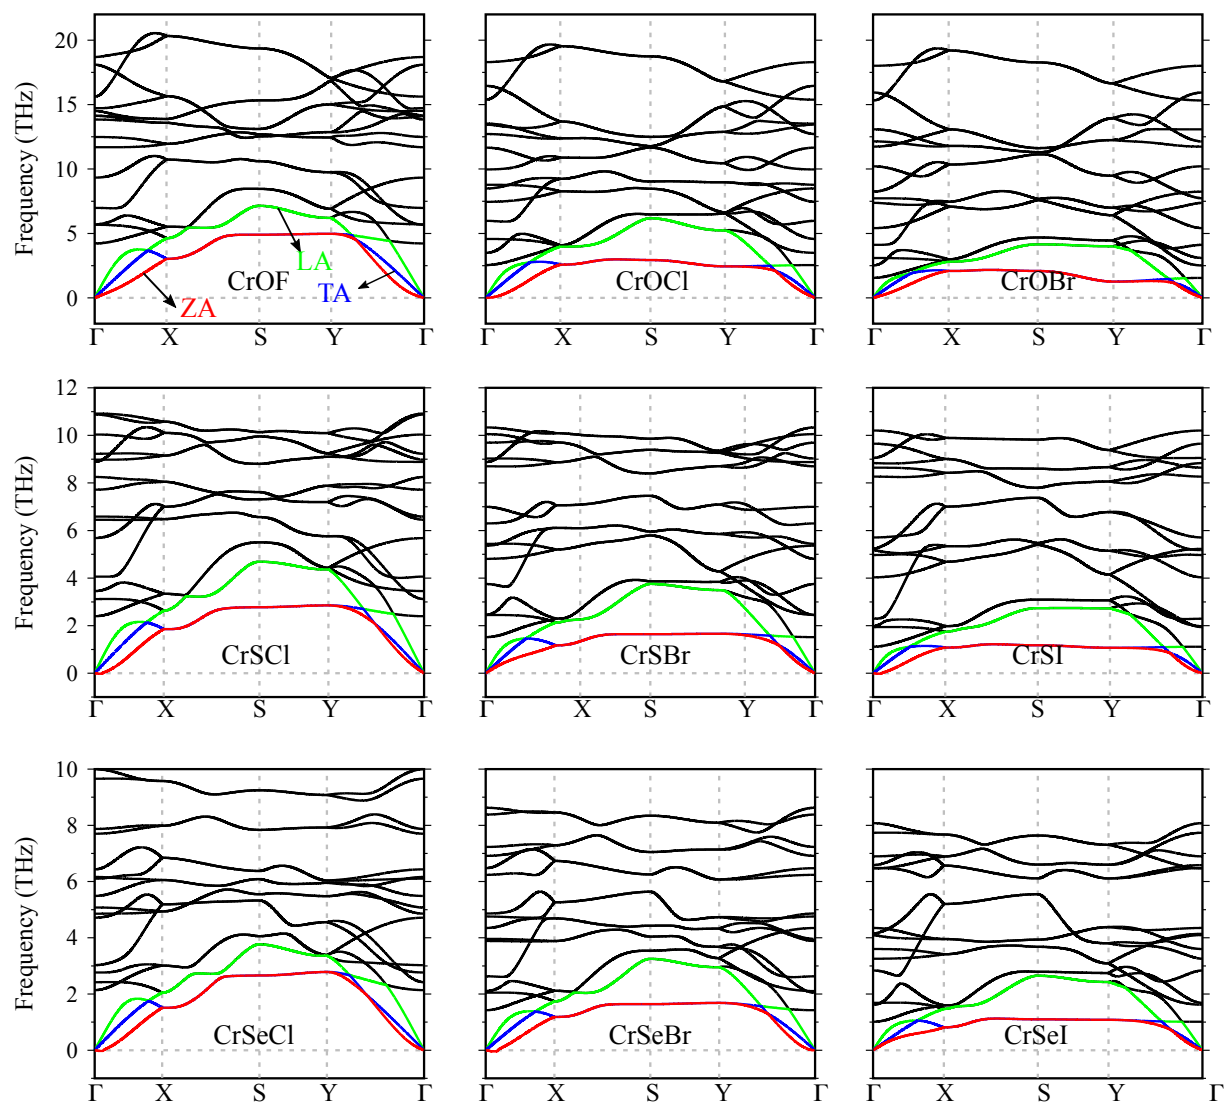

Fig. S1. Phonon dispersion spectra of 2D CrAX.

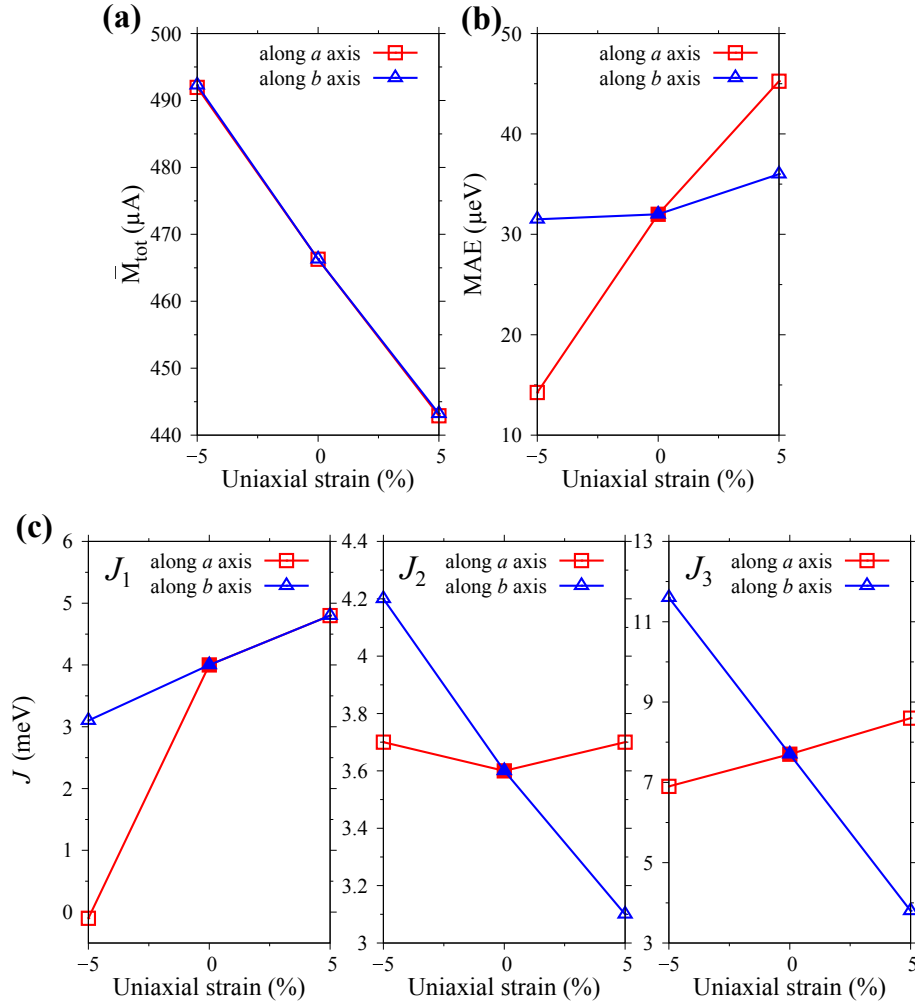

Fig. S2. Strain-tunable magnetic properties of CrOF: (a) net magnetic moment per unit area, (b) MAE, and (c) exchange parameters J_1 , J_2 and J_3 .

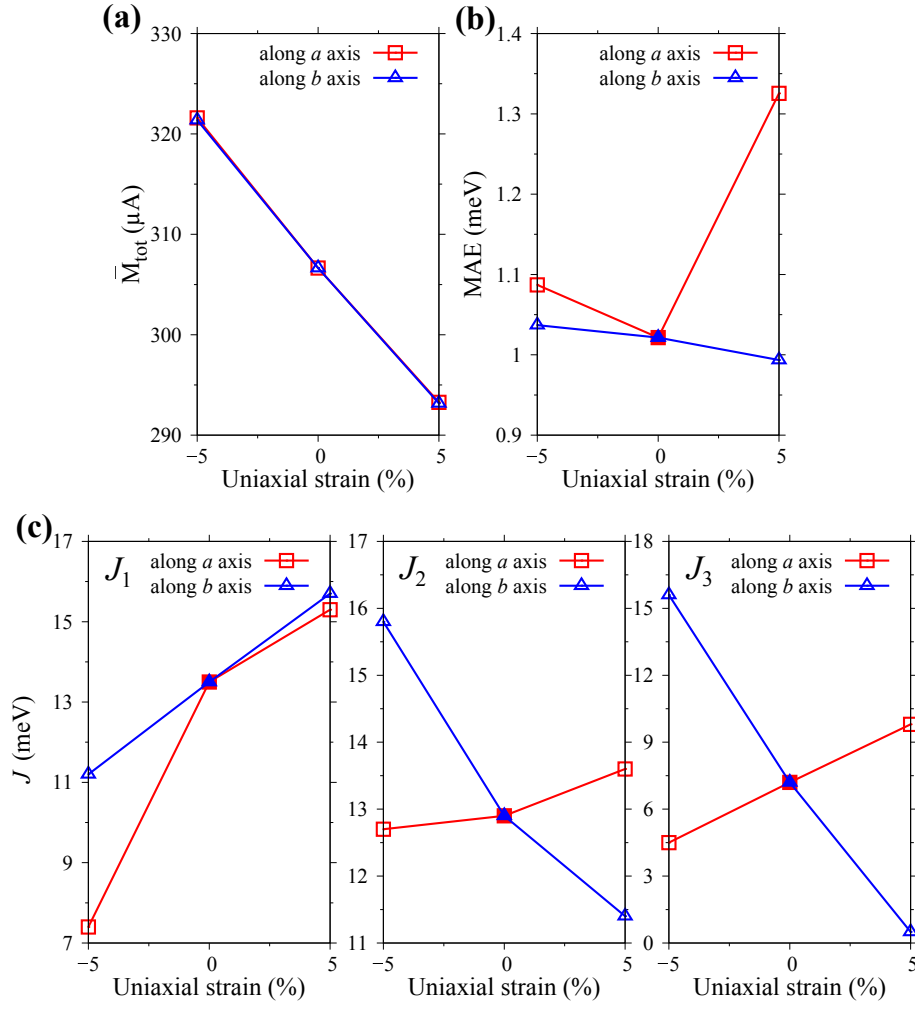

Fig. S3. Strain-tunable magnetic properties of CrSI: (a) net magnetic moment per unit area, (b) MAE, and (c) exchange parameters J_1 , J_2 and J_3 .

Fig. S4. Temperature effect in exchange interaction. The effect of displacement on (a) the nearest-neighbor (NN), (b) next NN, and (c) third NN exchange interaction of monolayer CrI_3 (figures from ref¹). (d) The calculated structure of the $3 \times 3 \times 1$ supercell CrI_3 and (e) the calculated displacement of each time step at 60 K by *ab-initio* molecular dynamics simulations. The average displacement of Cr is estimated as 0.065 Å. As previously discussed,^{1,2} exchange parameters could be affected by finite temperature induced atom displacements and are found only slightly changed when the Cr displacement is less than 0.1 Å.¹ However, the critical temperature of CrI_3 is around 60 K, at which Cr atoms are averagedly displaced by about 0.065 Å (d, e). This small displacement will not notably affect the magnetic properties, indicating the reasonable approximation of applying zero-K magnetic parameters in the classic spin Hamiltonians. Thus, the finite-temperature effect on MCE at low temperatures should be inconspicuous. Nevertheless, further in-depth studies are required to calculate the magnetic properties by considering the atom displacements from the vibration modes of 2D magnets if elevated temperatures are of interests.

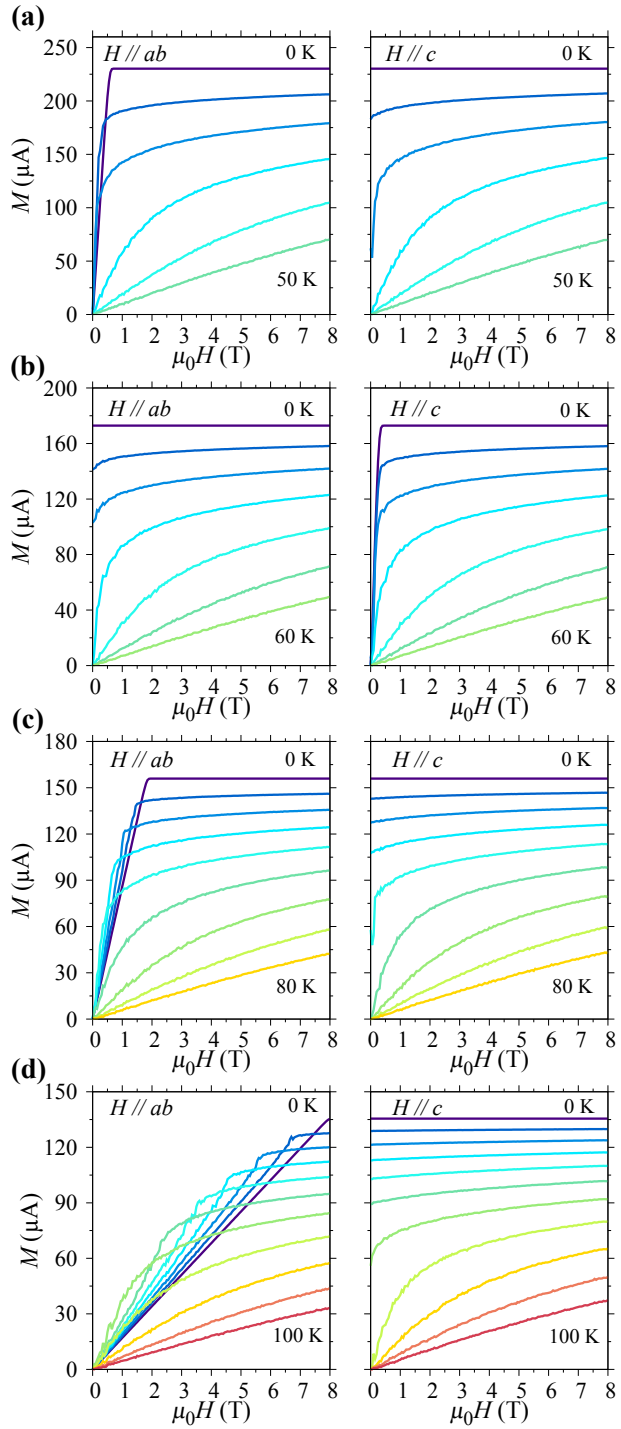

Fig. S5. Isothermal magnetization curves with field up to 8 T applied in the ab plane (left) and along the c axis (right) for (a) CrF_3 , (b) CrCl_3 , (c) CrBr_3 , and (d) CrI_3 . The curves are displayed every 10 K.

Fig. S6. Isothermal magnetization curves with field up to 5 T applied along the a axis (left), b axis (middle), and c axis (right) for (a) CrOF, (b) CrOCl, and (c) CrOBr. The curves are displayed every 10 K with a temperature range from 0 K to 300 K.

Fig. S7. Isothermal magnetization curves with field up to 5 T applied along the a axis (left), b axis (middle) and c axis (right) for (a) CrSCl, (b) CrSBr, and (c) CrSI. The curves are displayed every 10 K with a temperature range from 0 K to 300 K.

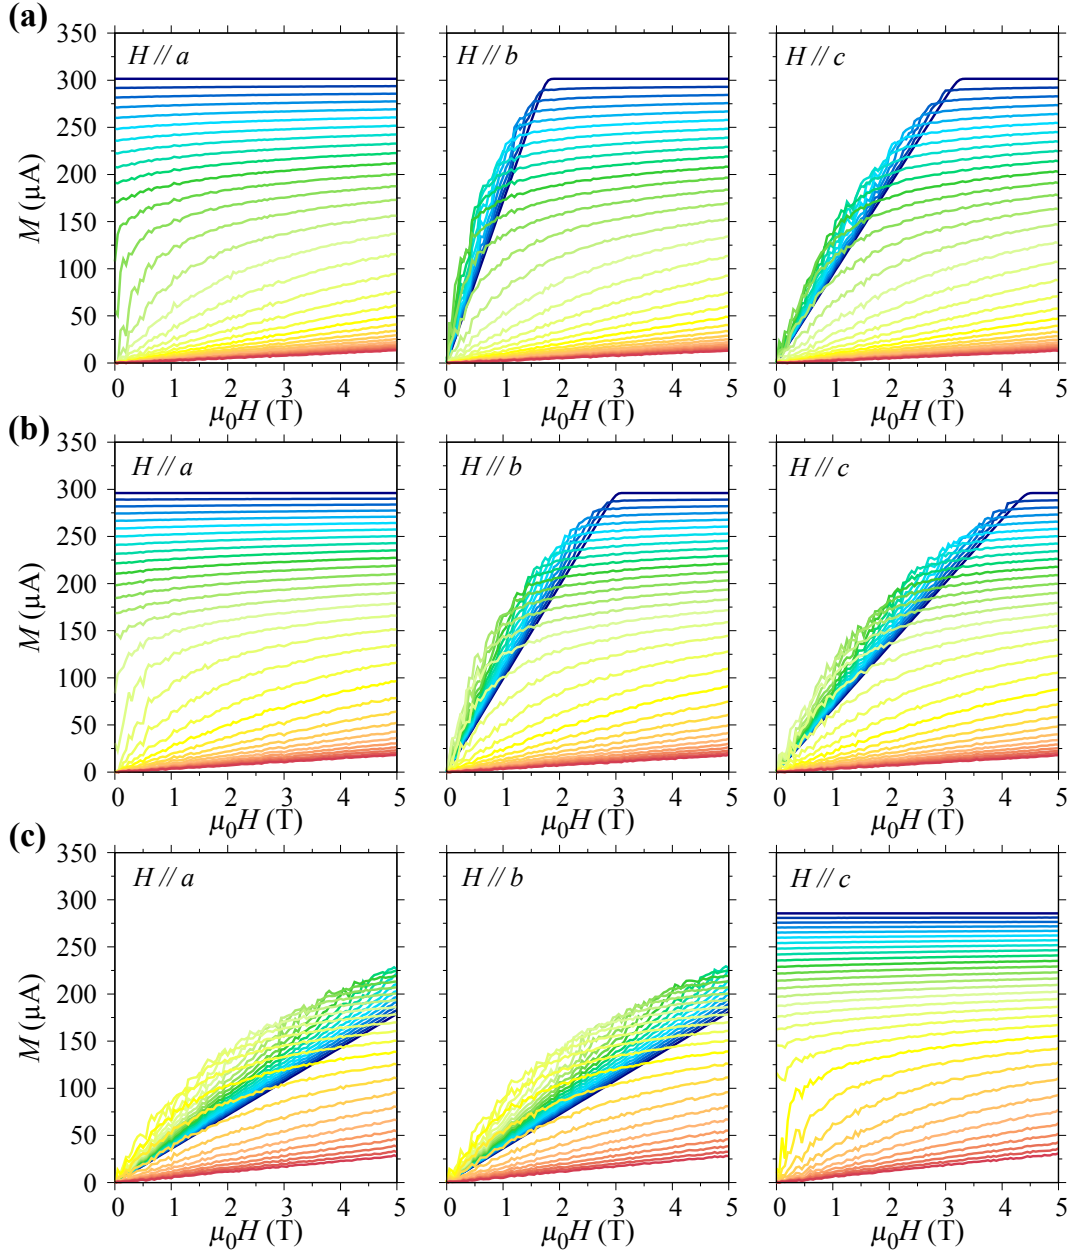

Fig. S8. Isothermal magnetization curves with field up to 5 T applied along the a axis (left), b axis (middle) and c axis (right) for (a) CrSeCl, (b) CrSeBr, and (c) CrSeI. The curves are displayed every 10 K with a temperature range from 0 K to 300 K.

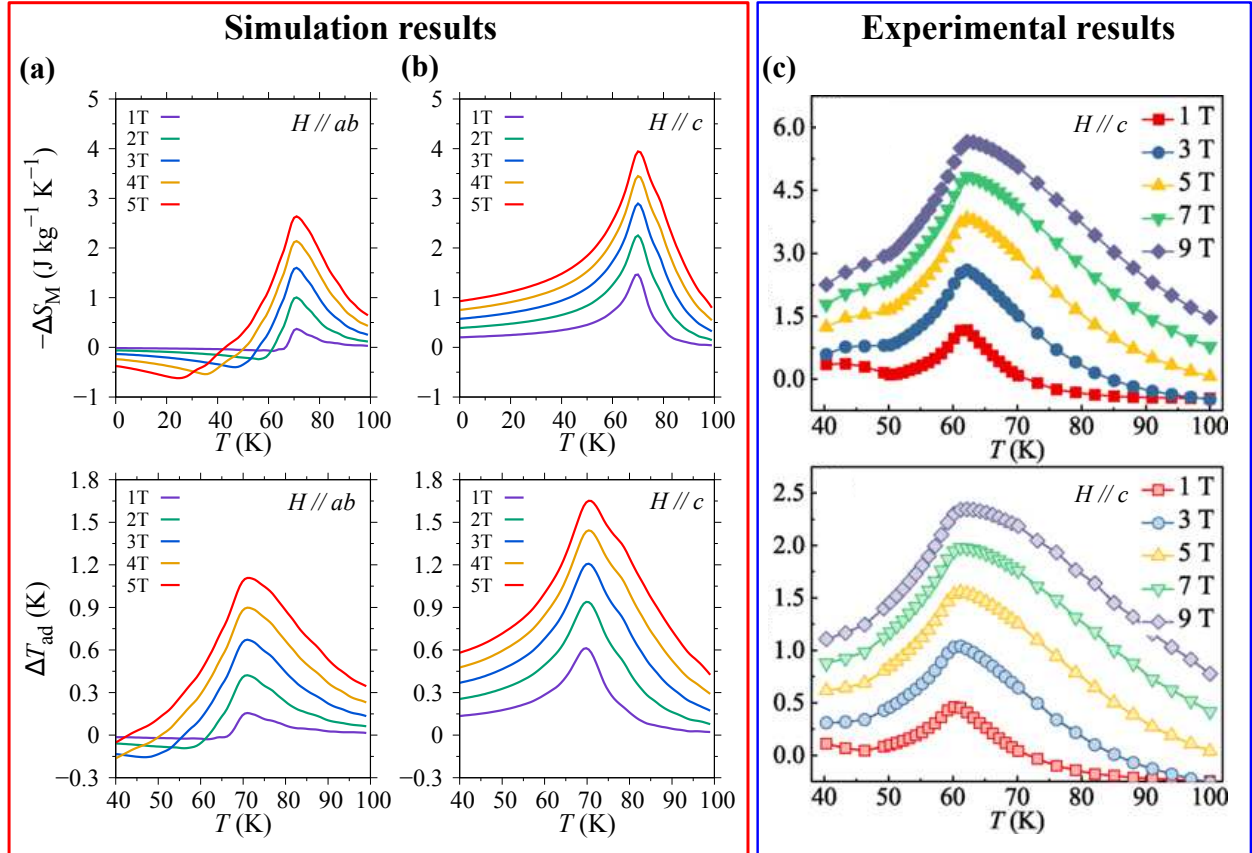

Fig. S9. Simulation and experimental results for MCE of bulk CrI_3 . Simulated temperature-dependent $-\Delta S_M$ (top) and ΔT_{ad} (bottom) for (a) $H \parallel ab$ and (b) $H \parallel c$ in different magnetic fields, respectively. Experimental temperature-dependent $-\Delta S_M$ (top) and ΔT_{ad} (bottom) for (c) $H \parallel c$ in different magnetic fields. Experimental curves in (c) are from ref.³

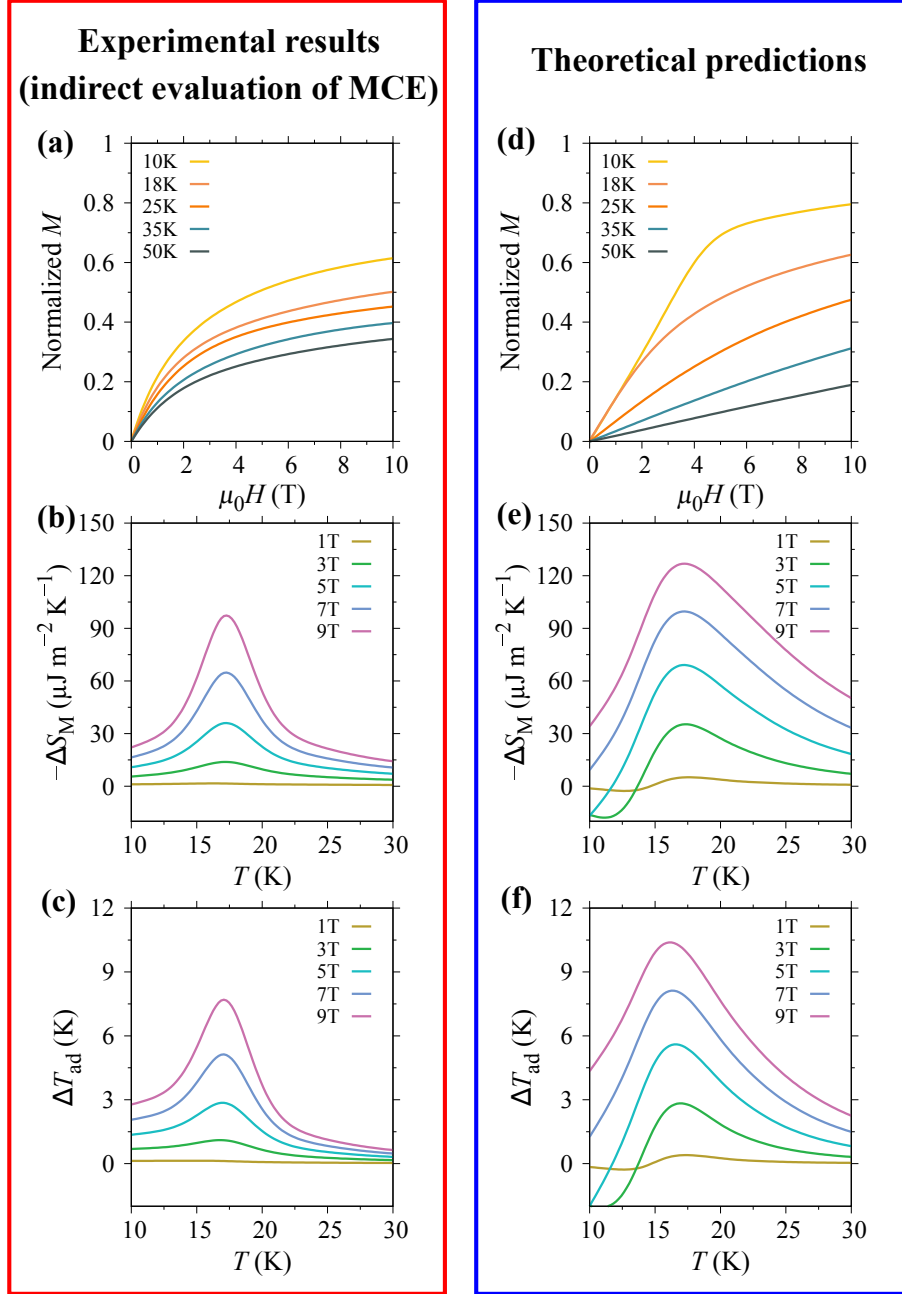

Fig. S10. MCE of monolayer Fe_3GeTe_2 from experimental results and theoretical predictions. Temperature-dependent M-H curves: (a) experiment; (d) prediction. $-\Delta S_M$ curves under different magnetic fields: (b) experiment; (e) prediction. ΔT_{ad} curves under different magnetic fields: (c) experiment; (f) prediction. The experimental data of monolayer Fe_3GeTe_2 are from ref. ⁴

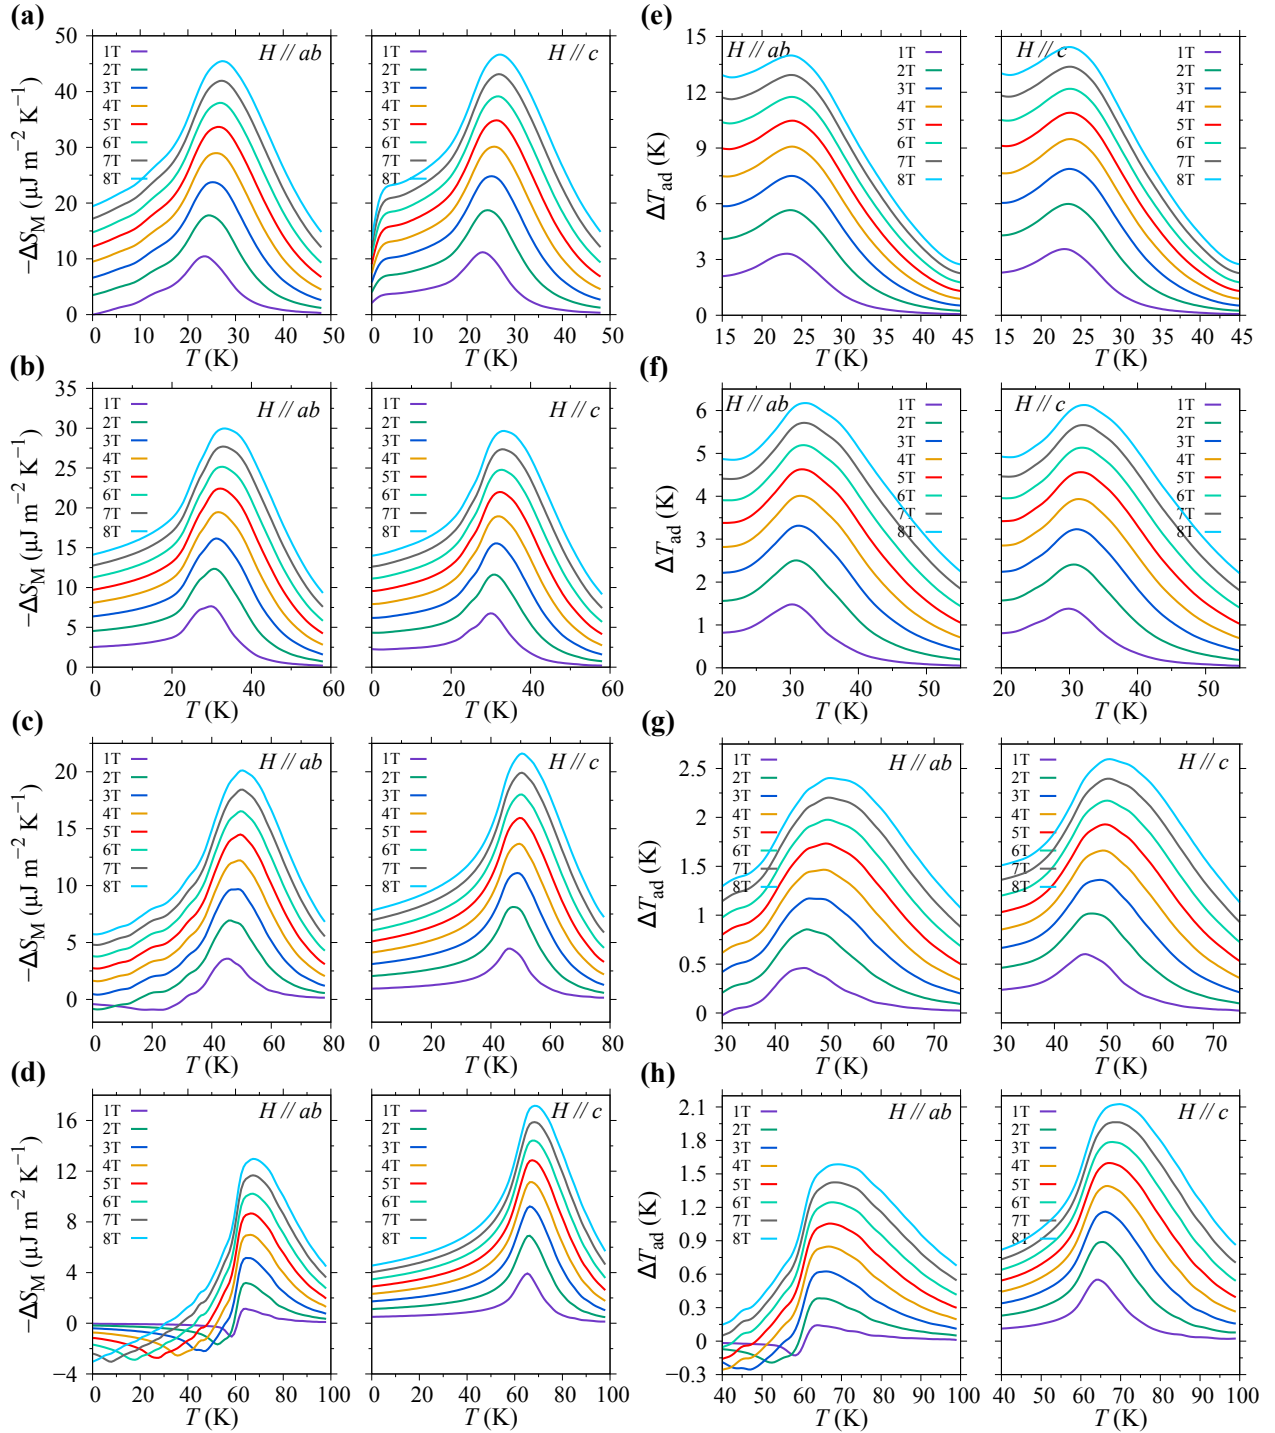

Fig. S11. Temperature dependences of (a-d) $-\Delta S_M$ and (e-h) ΔT_{ad} of monolayer CrX_3 for $H \parallel ab$ and $H \parallel c$ in different magnetic fields, respectively. (a) and (e) are for CrF_3 , (b) and (f) are for CrCl_3 , (c) and (g) are for CrBr_3 , (d) and (h) are for CrI_3 .

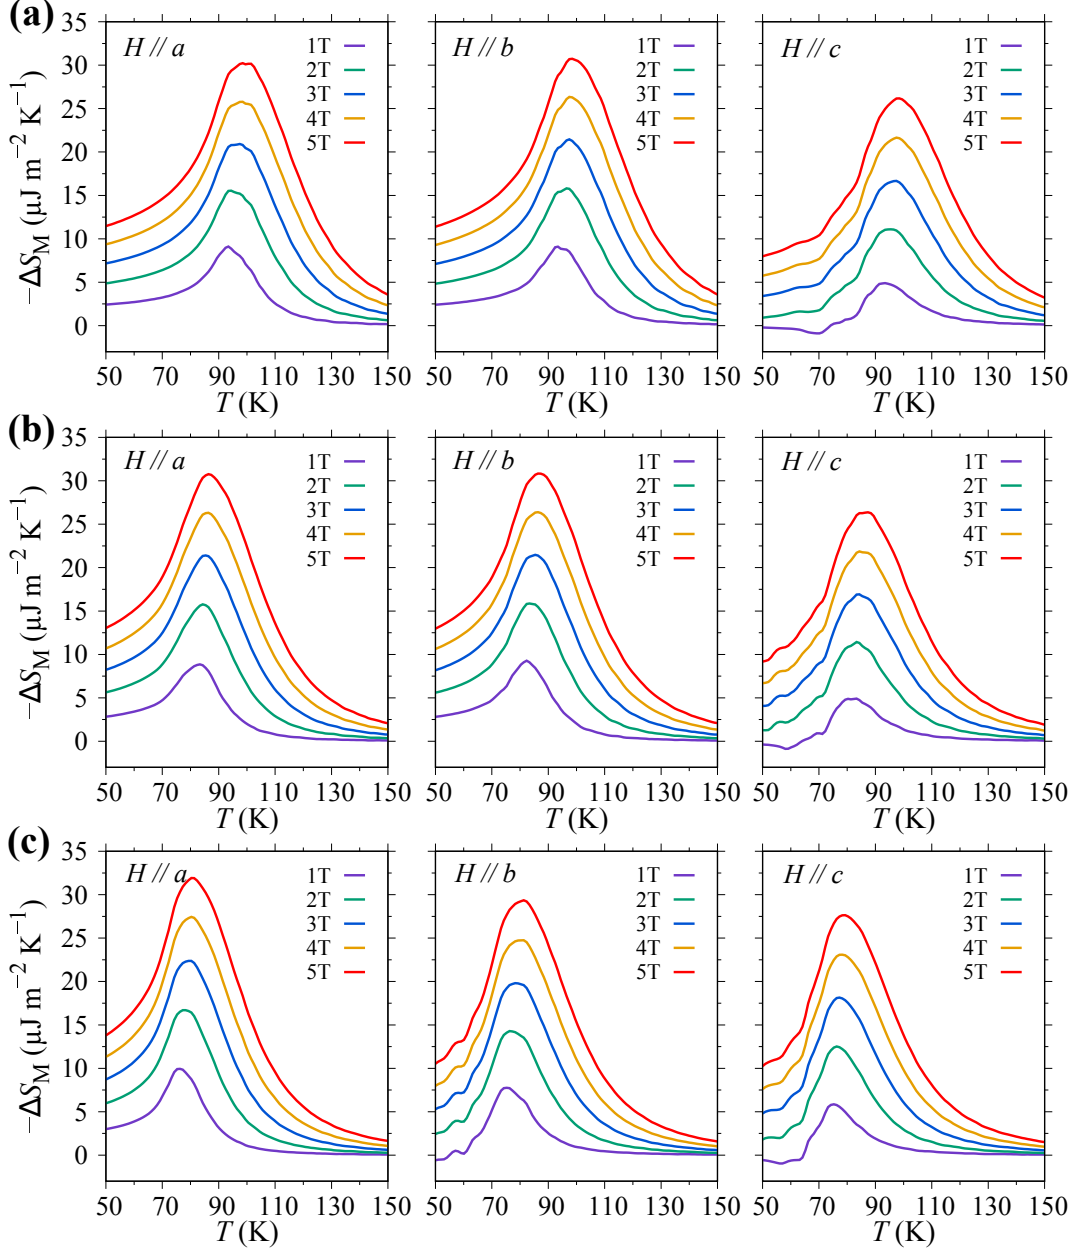

Fig. S12. Temperature dependences of $-\Delta S_M$ of monolayer (a) CrOF, (b) CrOCl and (c) CrOBr for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

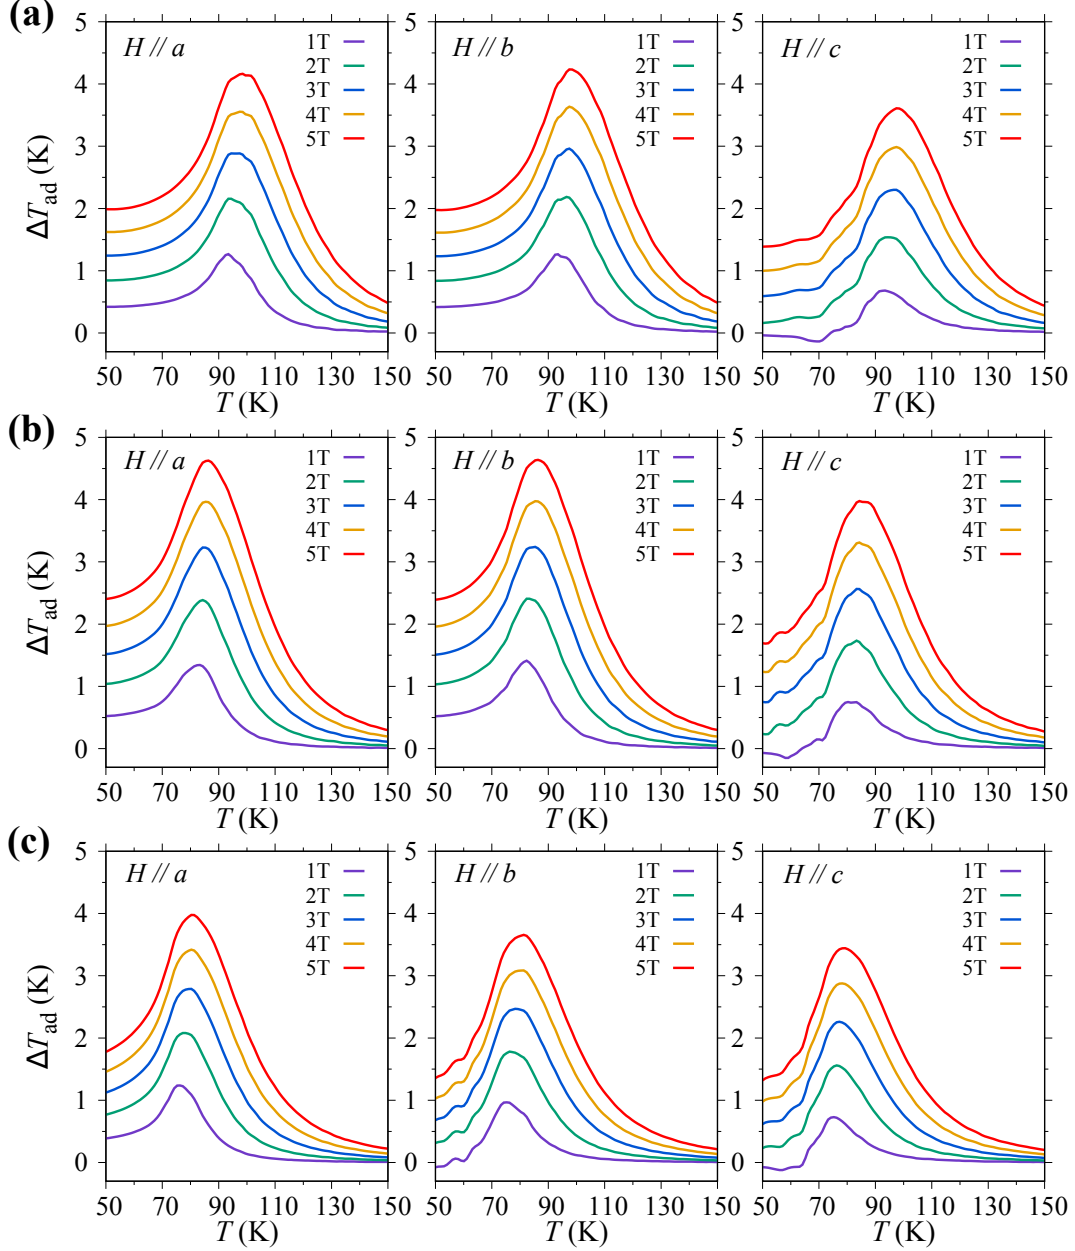

Fig. S13. Temperature dependences of ΔT_{ad} of monolayer (a) CrOF, (b) CrOCl and (c) CrOBr for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

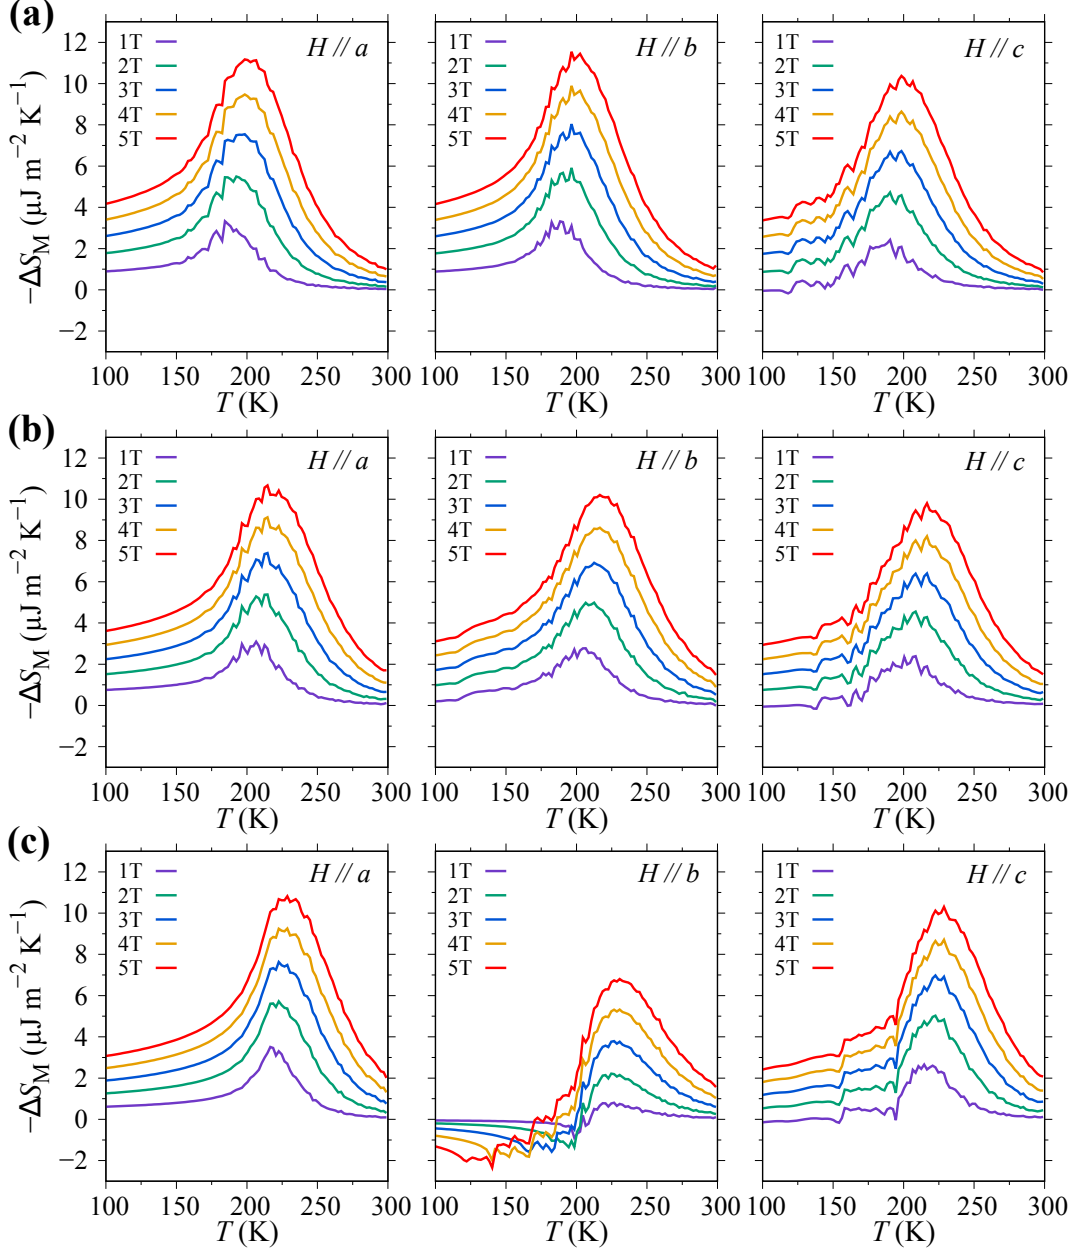

Fig. S14. Temperature dependences of $-\Delta S_M$ of monolayer (a) CrSCl, (b) CrSBr and (c) CrSI for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

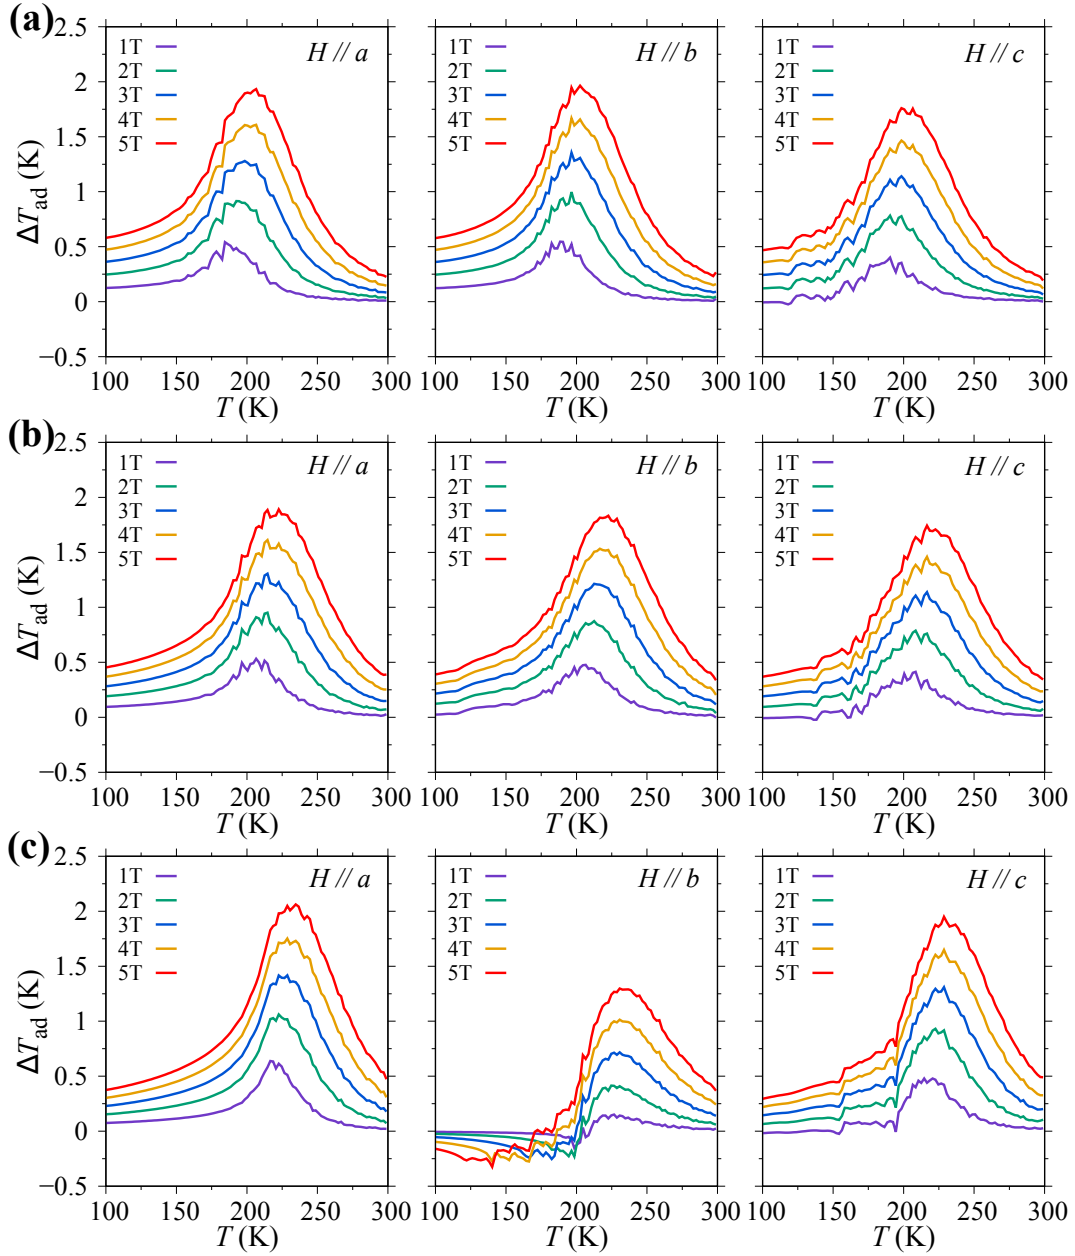

Fig. S15. Temperature dependences of ΔT_{ad} of monolayer (a) CrSCl, (b) CrSBr and (c) CrSI for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

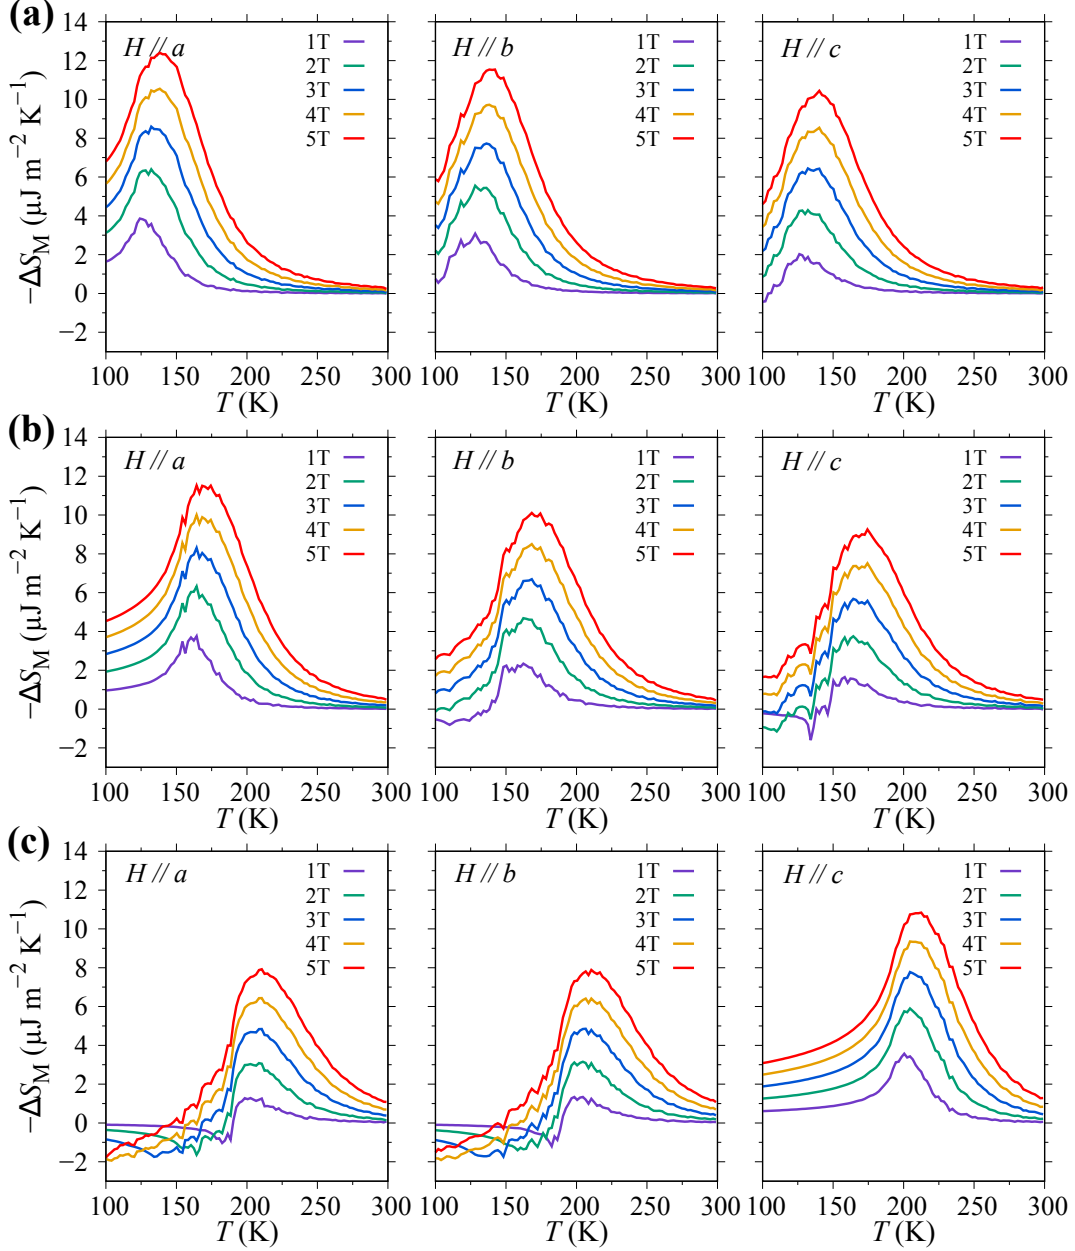

Fig. S16. Temperature dependences of $-\Delta S_M$ of monolayer (a) CrSeCl, (b) CrSeBr and (c) CrSeI for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

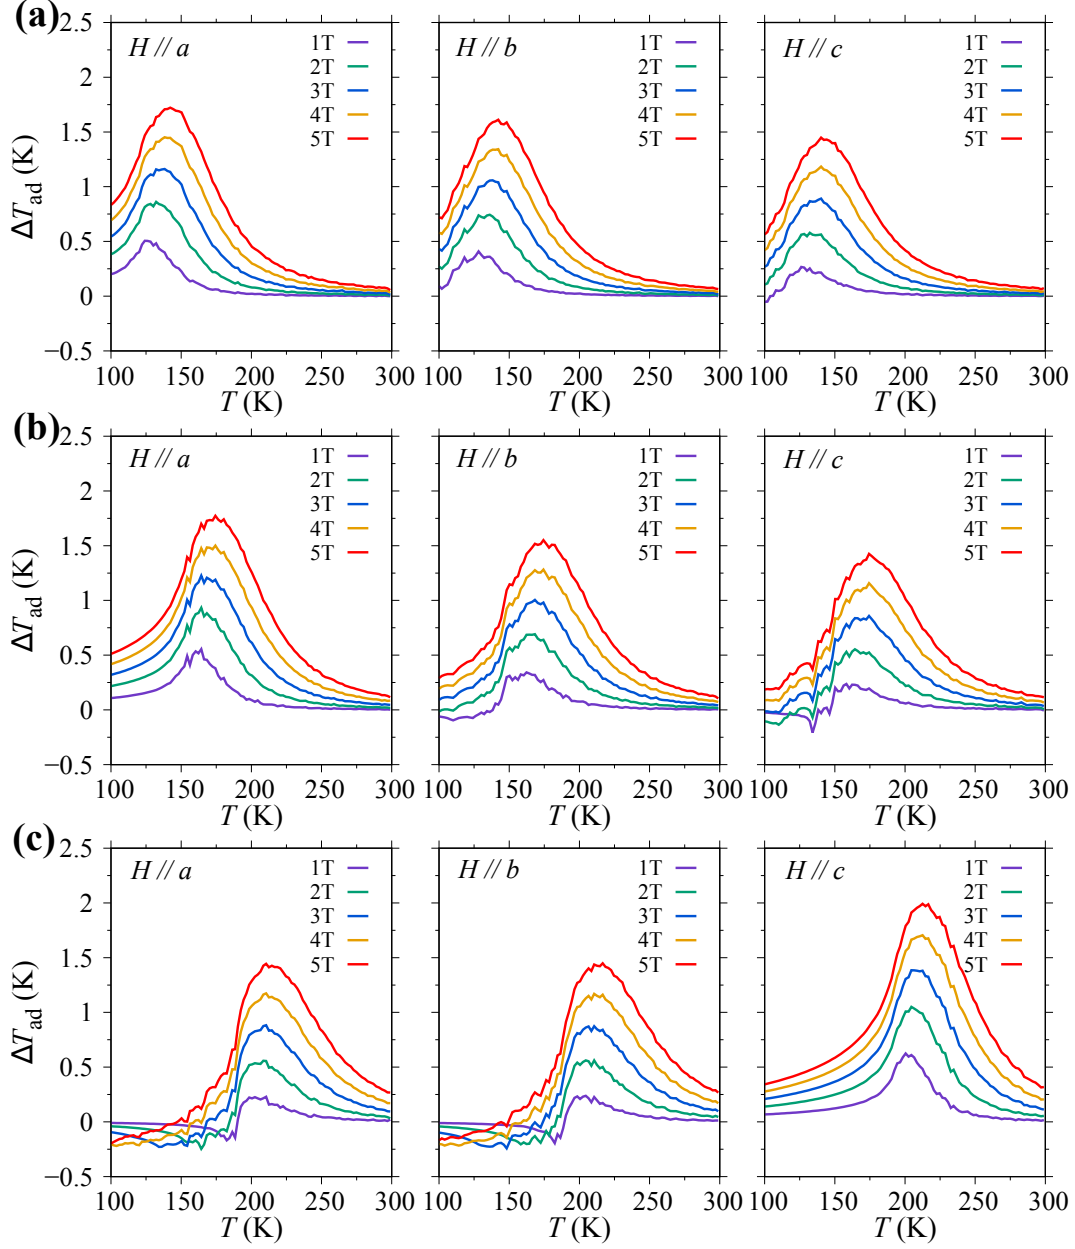

Fig. S17. Temperature dependences of ΔT_{ad} of monolayer (a) CrSeCl, (b) CrSeBr and (c) CrSeI for $H \parallel a$, $H \parallel b$, and $H \parallel c$ in different magnetic fields, respectively.

Fig. S18. Magnetic-field dependences of (a) $-\Delta S_M^{\max}$ and (b) $\Delta T_{\text{ad}}^{\max}$ of monolayers.

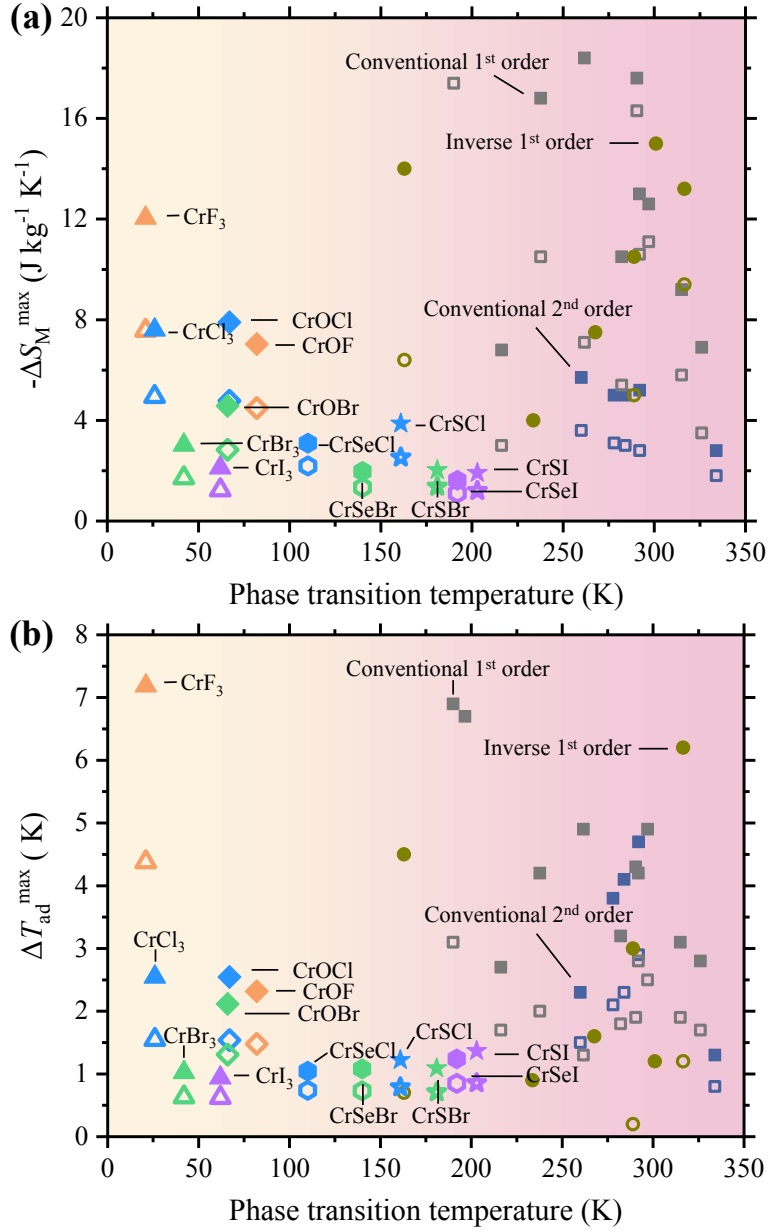

Fig. S19. The theoretical and ideal comparison of (a) $-\Delta S_M^{\max}$ and (b) ΔT_{ad}^{\max} between the monolayers and classical bulk magnetocaloric materials under low magnetic field (i.e., conventional 1st order materials, conventional 2nd order materials, inverse 1st order materials⁵). The hollow and solid points represent the data under 1 T and 2 T, respectively.

Fig. S20. Temperature dependences of heat capacity acquired by phonon calculations. The dashed lines are from previous bulk materials experimental measurements. The experimental data of single crystal of bulk CrF_3 ,⁶ CrCl_3 ,⁶ CrBr_3 ,⁷ CrI_3 ,³ CrOCl ⁸ and CrOBr ⁹ is drawn with dash lines.

Fig. S21. Phonon dispersion spectra of monolayer CrOF under the 5% (a) a -axis and (b) b -axis compressive strain.
