## ABSTRACT

**Background:** Although re-irradiation is increasingly used in clinical practice, almost no dedicated planning software exists.

45

**Purpose:** Standard dose-based optimization functions were adjusted for re-irradiation planning using accumulated equivalent dose in 2-Gy fractions (EQD2) with rigid or deformable dose mapping, tissue-specific  $\alpha/\beta$ , treatment-specific recovery coefficients, and voxelwise adjusted EQD2 penalization levels based on the estimated previously delivered EQD2 (EQD2<sub>deliv</sub>).

50

**Methods:** To demonstrate proof-of-concept, 35 Gy in 5 fractions was planned to a fictitious spherical relapse planning target volume (PTV) in three separate locations following previous prostate treatment on a virtual human phantom. The PTV locations represented one repeated irradiation scenario and two re-irradiation scenarios. For each scenario, three re-planning strategies with identical PTV dose-functions but various organ at risk (OAR) EQD2-functions was used:

55

- 1) reRT<sub>regular</sub>: Regular functions with fixed EQD2 penalization levels larger than EQD2<sub>deliv</sub> for all OAR voxels.
- 2) reRT<sub>reduce</sub>: As reRT<sub>regular</sub>, but with lower fixed EQD2 penalization levels aiming to reduce OAR EQD2.
- 3) reRT<sub>voxelwise</sub>: As reRT<sub>regular</sub> and reRT<sub>reduce</sub>, but with voxelwise adjusted EQD2 penalization levels based on EQD2<sub>deliv</sub>.

60

PTV near-minimum and near-maximum dose ( $D_{98\%}/D_{2\%}$ ), homogeneity index (HI), conformity index (CI) and accumulated OAR EQD2 ( $\alpha/\beta=3$  Gy) were evaluated.

65

**Results:** For the repeated irradiation scenario, all strategies resulted in similar dose distributions. For the re-irradiation scenarios, reRT<sub>reduce</sub> and reRT<sub>voxelwise</sub> reduced accumulated average and near-maximum EQD2 by ~1-10 Gy for all relevant OARs compared to reRT<sub>regular</sub>. The reduced OAR doses for reRT<sub>reduce</sub> came at the cost of distorted dose distributions with  $D_{98\%}=92.3\%$ ,  $HI=12.0\%$ ,  $CI=73.7\%$  and normal tissue hot spots  $\geq 150\%$  for the most complex scenario, while reRT<sub>regular</sub> ( $D_{98\%}=98.1\%$ ,  $HI=3.2\%$ ,  $CI=94.2\%$ ) and reRT<sub>voxelwise</sub> ( $D_{98\%}=96.9\%$ ,  $HI=6.1\%$ ,  $CI=93.7\%$ ) fulfilled PTV coverage without hot spots.

70

75

**Conclusions:** The proposed re-irradiation specific EQD2-based optimization functions introduces novel planning possibilities with flexible options to guide the trade-off between target coverage and OAR sparing with voxelwise adapted penalization levels based on EQD2<sub>deliv</sub>.

**Keywords:** re-irradiation; optimization functions; equivalent dose

## 1. INTRODUCTION

Radiotherapy treatment to a previously irradiated volume, so-called re-irradiation, is a promising technique, used in an increasing number of patients in a large variety of treatment sites.<sup>1</sup> Although  
85 few definitive guidelines exist and high-quality re-irradiation prospective data are lacking,<sup>1-3</sup>  
several of the well-recognized challenges associated with re-irradiation have been studied. These  
include the need to retrieve accurate image and dose data, handling of anatomical changes  
between the radiotherapy courses, integration of radiobiology when summing multiple  
radiotherapy courses, and deciding on clinically relevant dose constraints.<sup>3-7</sup> In contrast, almost  
90 no planning software specifically designed for re-irradiation exists, and even fewer efforts have  
been made on creating re-irradiation-specific optimization functions. Instead, various approaches  
requiring multiple manual steps for dose extraction and dose summation are often used.<sup>4,6</sup> Slightly  
more complex planning methods also exist where radiobiologically meaningful approaches are  
employed using, for example, the biological effective dose or the equivalent dose in 2-Gy  
95 fractions (EQD2).<sup>8</sup> Recent studies within the Support Tool for Re-Irradiation Decisions guided  
by Radiobiology (STRIDeR) project have, however, addressed some of these re-irradiation  
specific planning issues including early versions of the optimization functions presented here,  
which act on the 3D distribution of the accumulated EQD2.<sup>3,4</sup> Beyond acting on radiobiologically  
meaningful doses, other key issues when using standard optimization functions in re-irradiation  
100 planning are the lack of accounting for tissue recovery between treatment courses, and the use of  
penalization dose levels without accounting for the estimated previously delivered EQD2  
(EQD2<sub>deliv</sub>). In particular, the latter is an issue in situations where the previously delivered dose  
in a voxel is similar or higher than the requested total EQD2 level, which might cause misbehavior  
in the optimization as very low, or even negative, voxel doses are requested.

105 In this study, optimization functions adapted to re-irradiation treatment planning are  
presented in detail. The adapted functions act on accumulated EQD2, use tissue- and treatment  
course specific recovery coefficients, and voxelwise adapted EQD2 penalization levels as a  
function of EQD2<sub>deliv</sub>. Beyond this, the implementation includes feedback on the optimized EQD2  
metrics during optimization, and the option to override the EQD2<sub>deliv</sub> in an organ with a user-  
110 defined EQD2 if dose accumulation uncertainty is considered too large (e.g., due to uncertainties  
in the deformable image registration (DIR)).

## 2. METHODS

The proposed optimization functions designed for re-irradiation treatments were implemented in  
a research version of the treatment planning system RayStation 11A (RaySearch Laboratories  
115 AB, Stockholm, Sweden) and are described in the paragraphs below.

## 2.1. Re-irradiation optimization functions

The re-irradiation optimization functions are based on the EQD2 using the linear-quadratic model for cell survival. The use of EQD2 allows for dose summation of radiotherapy courses with different fractionation schedules and is often used for dose summations in re-irradiation treatments.<sup>1,3,4,9</sup>

### 2.1.1. Equivalent dose

For a total dose ( $D$ ) consisting of equal fractionation doses ( $d$ ), the EQD2 is expressed as,

$$\text{EQD2} = D \cdot \frac{\alpha/\beta + d}{\alpha/\beta + 2}, \quad (1)$$

where  $\alpha/\beta$  is an endpoint- and radiation quality-specific parameter that describes the sensitivity to changes in the dose per fraction. For re-irradiation planning, the total accumulated EQD2 (EQD2<sub>tot</sub>) should be accounted for,

$$\text{EQD2}_{\text{tot}} = \text{EQD2}_{\text{reRT}} + \sum_{j=1}^J (1 - r_j) \cdot \text{EQD2}_{\text{deliv},j}, \quad (2)$$

where EQD2<sub>reRT</sub> is the EQD2 from the planned re-irradiation treatment,  $J$  is the number of previous treatment courses, and  $r_j$  and EQD2<sub>deliv,j</sub> is the recovery coefficient and EQD2<sub>deliv</sub> for treatment course  $j$ , respectively. The organ- and treatment course specific recovery coefficient is a simplified way to account for partial time-dependent tissue recovery between the radiotherapy courses,<sup>10,11</sup> and lies between 0 and 1 (where zero reflects no recovery and one full recovery of the organ). The current implementation allows up to three unique user-defined recovery coefficients for each optimization function.

### 2.1.2. Dose accumulation

The implementation here supports both rigid and DIR for dose mapping.<sup>3,4</sup> Note that the previously delivered dose from course  $j$  in Eq. (2) can be estimated in various ways including the planned dose, dose-tracking on daily images, etc., and is always mapped to the re-irradiation CT before voxel-by-voxel conversion to EQD2<sub>deliv,j</sub> with region of interest (ROI)-specific  $\alpha/\beta$  ratios and ROI and treatment course specific recovery coefficients. Note also that the re-irradiation optimization function methodology presented in this study is conceptually invariant to the methodology used for dose accumulation. Hence, for simplicity and keeping focus on the optimization functions, the EQD2<sub>deliv</sub> was estimated from the planned dose using the same CT for both the primary and the re-irradiation treatments for the studied virtual human phantom case. Challenges with image registration for dose mapping has previously been discussed in a general context<sup>12</sup> and specifically for re-irradiation.<sup>3</sup>

### 2.1.3. Re-irradiation optimization functions

The standard physical optimization functions that impose a one-sided quadratic penalty on voxel dose deviations from a desired dose level<sup>13</sup> were adjusted for re-irradiation treatment planning to penalize the EQD2<sub>tot</sub> (from Eq. (2)) deviations from a desired EQD2 level (EQD2<sub>level</sub>). To accommodate optimization issues related to voxels where EQD2<sub>deliv</sub> is similar or higher than the desired EQD2<sub>level</sub>, the EQD2<sub>level</sub> was further allowed to be adjusted per ROI in a voxelwise fashion to account for the EQD2<sub>deliv</sub> with a minimum allowed unpenalized EQD2 level for the re-irradiation treatment (EQD2<sub>reRTmin</sub>) as,

$$\text{EQD2}_{\text{level}, i}^* = \max_{i \in \text{ROI}} \left\{ \text{EQD2}_{\text{level}, i}, \text{EQD2}_{\text{deliv}, i} + \text{EQD2}_{\text{reRTmin}} \right\}, \quad (3)$$

where EQD2<sub>level, i</sub><sup>\*</sup> is the adjusted EQD2 penalization level for voxel *i* and EQD2<sub>deliv, i</sub> is the estimated delivered EQD2 for voxel *i*. If the voxelwise adjustment is *not* selected, Eq. (3) is simply reduced to EQD2<sub>level, i</sub><sup>\*</sup> = EQD2<sub>level, i</sub>, where EQD2<sub>level, i</sub> is the regular EQD2 penalization level for voxel *i*. A schematic 1D representation of the EQD2<sub>level, i</sub><sup>\*</sup>, with and without this voxelwise adjustment to the EQD2<sub>deliv</sub>, is shown in

Figure 1 for a maximum EQD2 function and a EQD2-fall off function. In other aspects the re-irradiation functions behave as the standard dose-based optimization functions, which can be used in combination with the re-irradiation functions. The implementation was made for all standard optimization functions *f* in RayStation, which in their adapted form may be written as

$$f = \omega \cdot \sum_{i=1}^N g(\text{EQD2}_{\text{tot}, i}, \text{EQD2}_{\text{level}, i}^*) \cdot v_i \cdot \left( \frac{\text{EQD2}_{\text{tot}, i} - \text{EQD2}_{\text{level}, i}^*}{\text{EQD2}_{\text{level}, i}^*} \right)^2, \quad (4)$$

where  $\omega$  is the function weight,  $v_i$  is the relative volume of voxel *i* of an ROI consisting of *N* number of voxels, and EQD2<sub>tot, i</sub> and EQD2<sub>level, i</sub><sup>\*</sup> are the total EQD2 and adjusted EQD2 penalization level for voxel *i* calculated with Eqs. (2) and (3), respectively. The function *g* is given by  $g(\text{EQD2}_{\text{tot}, i}, \text{EQD2}_{\text{level}, i}^*) = H(\text{EQD2}_{\text{tot}, i} - \text{EQD2}_{\text{level}, i}^*)$ , where *H* is the Heaviside step function, for fall-off and maximum EQD2 functions, by  $g(\text{EQD2}_{\text{tot}, i}, \text{EQD2}_{\text{level}, i}^*) = H(\text{EQD2}_{\text{level}, i}^* - \text{EQD2}_{\text{tot}, i})$  for minimum EQD2 functions and by  $g(\text{EQD2}_{\text{tot}, i}, \text{EQD2}_{\text{level}, i}^*) = 1$  for uniform dose functions. The fall-off functions here use a linearly decreasing EQD2<sub>level</sub> outside of the target region until a selected distance from the target edge. From thereon, the EQD2<sub>level</sub> is constant and equal to the lowest selected EQD2<sub>level</sub> for the function. Note, although not used in this study, the corresponding optimization functions using equivalent uniform dose and dose-volume histograms (DVHs) were also adapted accordingly for re-irradiation.

An example of the adapted dialog for adding the functions including the re-irradiation specific parameters is shown in Supplementary Figure 1. To allow flexibility if e.g. the

uncertainty in the dose mapping is considered to be too large due to anatomy changes, the user can override the accumulated  $EQD2_{\text{deliv}}$  in Eq. (2) with one out of two options; (1) the minimum  $EQD2_{\text{deliv}}$  to the  $0.1 \text{ cm}^2$  of the ROI volume receiving the highest doses, or (2) any user-specified  $EQD2$  value. If one of these options is selected (using corresponding check box or text box in Supplementary Figure 1), Eq. (2) is automatically simplified to  $EQD2_{\text{tot}} = EQD2_{\text{reRT}} + EQD2_{\text{oride}}$  where  $EQD2_{\text{oride}}$  is the override value used for all voxels in the ROI.

## 2.2. Re-irradiation treatment planning

To demonstrate proof-of-concept of the novel re-irradiation functions, a fictitious prostate photon dual volumetric modulated arc therapy (VMAT) treatment of 60 Gy in 20 fractions ( $EQD2 = 72$  Gy with  $\alpha/\beta = 3$  Gy) was planned on a virtual human male pelvis CIRS 801-P phantom (CIRS, Inc., Norfolk, VA, USA). The clinical target volume (CTV) consisted of the prostate and seminal vesicles and the planning target volume (PTV) was created as an isotropic expansion of the CTVs (1 cm for seminal vesicles and 0.5 cm for prostate). Beyond this, the rectum, bladder, small bowel, and femoral heads were delineated and considered as organs at risk (OARs).

Subsequently, a fictitious spherical relapse gross tumor volume (GTV) of about  $38 \text{ cm}^3$  (radius of 2.1 cm) was positioned in three distinct locations with identical coordinates in the superior-inferior direction to schematically represent ‘repeat irradiation’ (RI), ‘re-irradiation type 2’ (RIT2), and ‘re-irradiation type 1’ (RIT1) scenarios as defined by a recent European consensus report on re-irradiation<sup>1</sup>. The volume of the GTV corresponds to the median pelvic re-irradiation GTV from a systematic review on hypofractionated pelvic re-irradiation,<sup>14</sup> and the selected locations were inspired by the patterns of pelvic relapses<sup>15</sup> but had no anatomical meaning. In line with the recent increased interest in hypofractionated and ablative re-irradiation treatments,<sup>14,16,17</sup> three dual-arc VMAT plans of 35 Gy in 5 fractions ( $EQD2 = 70$  Gy with  $\alpha/\beta = 3$  Gy) were optimized for each relapse PTV (3 mm isotropic expansion of the corresponding GTV) using the full 3D dose distribution from the first treatment course as the estimated previously delivered dose (i.e.  $EQD2_{\text{deliv}}$  in Eq. (2)). As for the first treatment course, a voxel size of  $2 \times 2 \times 2 \text{ mm}^3$  was used. The three re-planning strategies used an identical uniform PTV dose objective of 35 Gy but differed in the use of the novel re-irradiation functions for the OARs:

(1)  $\text{reRT}_{\text{regular}}$ : A regular  $EQD2$  fall-off function acting on the whole phantom outline was combined with regular  $EQD2$ -based maximum objective functions for the bladder, rectum, small bowel, and the femoral heads *without* using the voxelwise adapted  $EQD2_{\text{level}}^*$  in Eq. (3). Instead, a fixed  $EQD2_{\text{level}}^* = EQD2_{\text{deliv,max}} + EQD2_{\text{reRTmin}}$  Gy was used in Eq. (4) for the maximum functions, where  $EQD2_{\text{deliv,max}}$  is the maximum estimated delivered  $EQD2$  to the OAR of interest and  $EQD2_{\text{reRTmin}} \in [1, 10]$  Gy was selected depending on the relapse PTV

210 location and OAR. Hence, all voxels for each maximum OAR function had a fixed  $\text{EQD2}_{\text{level}}^* > \text{EQD2}_{\text{deliv}}$ .

(2)  $\text{reRT}_{\text{reduce}}$ : As (1) but with a fixed  $\text{EQD2}_{\text{level}}^*$  per maximum OAR function of  $\text{EQD2}_{\text{level}}^* = \text{EQD2}_{\text{deliv}, 25\%}$  used in Eq. (4), where  $\text{EQD2}_{\text{deliv}, 25\%}$  denotes the minimum  $\text{EQD2}_{\text{deliv}}$  to the 25% of the OAR receiving the highest  $\text{EQD2}_{\text{deliv}}$ , aiming to further reduce  $\text{EQD2}_{\text{tot}}$  compared to  
215 (1). Hence,  $\frac{3}{4}$  of the voxels for each maximum OAR function had  $\text{EQD2}_{\text{level}}^* > \text{EQD2}_{\text{deliv}}$  and  $\frac{1}{4}$  had  $\text{EQD2}_{\text{level}}^* \leq \text{EQD2}_{\text{deliv}}$ .

(3)  $\text{reRT}_{\text{voxelwise}}$ : Combining OAR objectives from (1) and (2) with  $\text{EQD2}_{\text{level}}$  equal to the  $\text{EQD2}_{\text{level}}^*$  from (2) per OAR with the corresponding OAR  $\text{EQD2}_{\text{reRTmin}}$  from (1) as input to the voxelwise adaptation of  $\text{EQD2}_{\text{level}}^*$  in Eq. (3). Hence, all voxels for each OAR had a  
220 voxelwise adjusted  $\text{EQD2}_{\text{level}}^* > \text{EQD2}_{\text{deliv}}$  for the fall-off function and the maximum OAR functions.

Supplementary Figure 2 shows the optimization functions used for all three re-planning strategies in the RIT1 scenario including visualization of the optimized  $\text{EQD2}_{\text{tot}}$  metrics to guide the user during re-irradiation optimization.

### 225 2.3. Plan evaluation

The PTV coverage of the re-irradiation plans was evaluated using  $D_{98\%}$ ,  $D_{2\%}$ , the homogeneity index  $\left(\text{HI} = \frac{D_{2\%} - D_{98\%}}{D_{50\%}}\right)$  and the conformity index  $\left(\text{CI} = \frac{2 \cdot |\text{TV} \cap \text{V}_{\text{target}}|}{|\text{TV}| + |\text{V}_{\text{target}}|}\right)$ , where  $D_{x\%}$  is the minimum dose to  $x\%$  of the PTV receiving the highest doses, the sets  $\text{TV}$  and  $\text{V}_{\text{target}}$  denote the treated volume and target volume, respectively, and  $|A|$  is the volume of a set  $A$ . The TV was defined as  
230 the volume of the 98% isodose line. The clinical PTV goals were  $D_{98\%} \geq 95\%$  of 35 Gy and  $D_{2\%} \leq 105\%$  of 35 Gy,  $\text{HI} \leq 10\%$ , and  $\text{CI} \geq 90\%$ .

Subsequently, all re-irradiation plans were converted to  $\text{EQD2}_{\text{reRT}}$  and summed with the  $\text{EQD2}_{\text{deliv}}$  of the first treatment course using Eq. (2) with  $r = 0$  and  $\alpha/\beta = 3$  Gy for all voxels giving  $\text{EQD2}_{\text{tot}}$ . DVHs using  $\text{EQD2}_{\text{tot}}$  were evaluated for the rectum, bladder, small bowel, and the  
235 femoral heads including comparisons of the average  $\text{EQD2}_{\text{tot}}$  and the near-maximum  $\text{EQD2}_{\text{tot}}$  ( $\text{EQD2}_{\text{tot}, 2\%}$ ).

## 3. RESULTS

Figure 1 shows schematical 1D examples of the implementation of the EQD2-based re-irradiation optimization functions for the maximum and fall-off functions used in  $\text{reRT}_{\text{regular}}$ ,  $\text{reRT}_{\text{reduce}}$  and  $\text{reRT}_{\text{voxelwise}}$ . Note that the  $\text{EQD2}_{\text{level}}^*$  is lower than the  $\text{EQD2}_{\text{deliv}}$  for large parts in  
240 Figure 1a for  $\text{reRT}_{\text{reduce}}$  and in

Figure 1b, for both  $\text{reRT}_{\text{regular}}$  and  $\text{reRT}_{\text{reduce}}$ , since the  $\text{EQD2}_{\text{level}}^*$  is not using the novel voxelwise adjustment in Eq. (3). For  $\text{reRT}_{\text{voxelwise}}$ , the  $\text{EQD2}_{\text{level}}^*$  instead adapts voxelwise to  $\text{EQD2}_{\text{deliv}}$  with

245

an offset equal to  $\text{EQD2}_{\text{reRTmin}}$  (equal to 4 Gy in

Figure 1) for voxels where  $\text{EQD2}_{\text{level}} < \text{EQD2}_{\text{deliv}} + \text{EQD2}_{\text{reRTmin}}$  according to Eq. (3).

Figure 2 shows the EQD2 distribution for the first treatment course together with the superimposed EQD2 distributions for the three scenarios for each treatment strategy. Figure 3 shows the corresponding DVHs for the PTVs (using RI, RIT1 and RIT2 doses only) and two relevant OARs (using  $\text{EQD2}_{\text{tot}}$ ) for each relapse scenario. The evaluated PTV dose metrics are summarized in Table 1. For the RI scenario, all three plans had similar EQD2 distributions and OAR doses (Figure 2 and Figure 3b) and fulfilled the clinical goals with similar dose metrics (Table 1 and Figure 3a). For the more complex re-irradiation scenarios RIT1 and RIT2, note the generally reduced EQD2 to the OARs for  $\text{reRT}_{\text{reduce}}$  and  $\text{reRT}_{\text{voxelwise}}$  compared to  $\text{reRT}_{\text{regular}}$  (Figure 2). As indicated by Figure 3c and Figure 3d the largest reductions were achieved with  $\text{reRT}_{\text{reduce}}$  where the average  $\text{EQD2}_{\text{tot}}$  and  $\text{EQD2}_{\text{tot}, 2\%}$  for the OARs were generally reduced by about 1-10 Gy and 3-12 Gy, respectively, compared to  $\text{reRT}_{\text{regular}}$ . For  $\text{reRT}_{\text{voxelwise}}$ , the corresponding OAR reductions compared to  $\text{reRT}_{\text{regular}}$  were about 1-4 Gy in the average  $\text{EQD2}_{\text{tot}}$  and 2-8 Gy in the  $\text{EQD2}_{\text{tot}, 2\%}$ . For  $\text{reRT}_{\text{voxelwise}}$ , this OAR sparing was achieved with comparable PTV coverage to  $\text{reRT}_{\text{regular}}$  (Table 1 and Figure 3a) without adding any extra optimization time, while for  $\text{reRT}_{\text{reduce}}$ , the OAR sparing distorted the dose distributions causing PTV underdosage and increased HI for RIT1, and lowered the CI with normal tissue hot spots from the re-irradiation treatment alone of over 100 Gy EQD2 for both RIT1 and RIT2 (Table 1, Figure 2c, and Figure 3a).

250

255

260

265

#### 4. DISCUSSION

The proposed optimization functions introduce a novel and flexible approach to re-irradiation treatment planning that account for accumulated estimated previously delivered dose in a radiobiologically meaningful way by using summed EQD2 across multiple treatment courses with tissue-specific recovery coefficients and  $\alpha/\beta$  ratios. During the recent ESTRO Physics workshop on re-irradiation,<sup>7</sup> such dose accumulation capability (together with visualization) was identified as one of the highest priorities when scoring potential software tools to support safe clinical re-irradiation. Although some previous studies have reported similar approaches for the evaluation of re-irradiation treatments,<sup>18,19</sup> few have incorporated such functionalities into re-irradiation planning using commercially available software.<sup>3,4</sup>

270

275

For the fictitious RI scenario in this study, the three re-planning strategies performed equally well (Table 1, Figure 2, Figure 3a and Figure 3b), which was expected due to the large distances between PTV and relevant OARs associated with RI treatments.<sup>1</sup> However, note the

slightly elongated EQD2 distribution for  $\text{reRT}_{\text{reduce}}$  compared to  $\text{reRT}_{\text{regular}}$  and  $\text{reRT}_{\text{voxelwise}}$  for the RI scenario. This is due to the large penalty associated with the OAR voxels where  $\text{EQD2}_{\text{level}}^* < \text{EQD2}_{\text{deliv}}$  (1/4 of the voxels for each OAR in this case), where the optimization formulation corresponds to a request for negative voxel doses since the desired EQD2 is lower than the already estimated delivered EQD2. Although this issue has minor impact in the RI scenario, it is the main reason for the markedly elongated dose distributions with normal tissue hot spots reaching over 100 Gy EQD2 for  $\text{reRT}_{\text{reduce}}$  in the RIT1 and RIT2 scenarios (Figure 2c), which also caused the suboptimal PTV coverage in RIT1 (Table 1 and Figure 3a). This is also reflected in the evaluated OAR function values shown in Supplementary Figure 2 for the RIT1 scenario, where all maximum OAR function values are substantially higher for  $\text{reRT}_{\text{reduce}}$  compared to  $\text{reRT}_{\text{regular}}$  and  $\text{reRT}_{\text{voxelwise}}$ . That said, the accumulated OAR EQD2 is lowest for  $\text{reRT}_{\text{reduce}}$ , as shown by the feedback of the minimum  $\text{EQD2}_{\text{tot}}$  at  $0.1 \text{ cm}^3$  in Supplementary Figure 2 and by the DVHs in Figure 3d. The high function values, extremely elongated dose distributions, normal tissue hot spots, and target underdosage are strong arguments to avoid regular re-irradiation optimization functions with  $\text{EQD2}_{\text{level}}^* < \text{EQD2}_{\text{deliv}}$ . While the selection of  $\text{EQD2}_{\text{level}} = \text{EQD2}_{\text{deliv}, 25\%}$  for  $\text{reRT}_{\text{reduce}}$  was somewhat arbitrary, comparable outcomes could have been achieved as long as  $\text{EQD2}_{\text{level}}$  remained below  $\text{EQD2}_{\text{deliv}}$  for certain voxels. However, if the selected ratio of voxels with  $\text{EQD2}_{\text{level}}^* < \text{EQD2}_{\text{deliv}}$  were gradually reduced from 1/4, the PTV coverage would be improved with a more symmetric dose distribution, fewer hot spots, and lower OAR function values. However, finding the optimal trade-off might be a time-consuming effort, and should be avoided as negative doses are requested as long as  $\text{EQD2}_{\text{level}}^* < \text{EQD2}_{\text{deliv}}$  in some voxels. This is both unphysical and undesirable from an optimization point of view since the re-irradiation dose contribution cause large penalties due to the quadratic formulation of the objective functions (see Eq. (4) and Supplementary Figure 2).

Instead, the  $\text{reRT}_{\text{regular}}$  planning strategy ensured  $\text{EQD2}_{\text{level}}^* > \text{EQD2}_{\text{deliv}}$  for all voxels for the maximum OAR functions. However, the OAR sparing of  $\text{reRT}_{\text{regular}}$  was substantially worse compared to the  $\text{reRT}_{\text{reduce}}$  strategy (Figure 3). To handle this, the favorable attributes of the two other re-planning strategies were combined by introducing the voxelwise adapted  $\text{EQD2}_{\text{level}}^*$  for  $\text{reRT}_{\text{voxelwise}}$ . This resulted in satisfactory PTV coverage (Table 1) while simultaneously avoiding the suboptimal solutions of  $\text{reRT}_{\text{regular}}$  (insufficiently strict on OAR doses) and  $\text{reRT}_{\text{reduce}}$  (excessively strict on OAR doses causing normal tissue hot spots) for the complex re-irradiation scenarios (Figure 2 and Figure 3). By using the override-option where the  $\text{EQD2}_{\text{deliv}}$  in an ROI is replaced with a suitable fixed EQD2, one can in some cases produce similar plans as the  $\text{reRT}_{\text{voxelwise}}$  strategy by setting a fixed  $\text{EQD2}_{\text{level}}^* = \text{EQD2}_{\text{reRTmin}} + \text{EQD2}_{\text{oride}}$ . However, since the spatial information of the  $\text{EQD2}_{\text{deliv}}$  is then lost, this option should only be used in cases where the 3D dose mapping is not used due to e.g. large DIR uncertainties.

315 This study focused on the optimization function design and some specific options using a phantom case without consideration of DIR for dose mapping, recovery coefficients, tissue-specific  $\alpha/\beta$  values, multiple treatment courses etc. For such simplified scenarios, it might often be possible to generate acceptable re-irradiation treatment plans using regular dose-based functions, although this was beyond the scope in this study. However, this is often more time-consuming, involves multiple manual steps and becomes extremely challenging in clinical reality  
320 when dealing with anatomical changes between treatment courses, heterogeneously delivered doses from several treatment courses of varying fractionation schedules, with different recovery coefficients and tissue-specific  $\alpha/\beta$ .<sup>4,6</sup> Hence, it can be argued that the functions presented here are of greatest benefit when the re-irradiation complexity increases since manual procedures then becomes extremely troublesome and time-consuming. This is indicated by recent studies using  
325 preliminary EQD2-based optimization functions in a full clinical re-irradiation workflow within the STRIDeR project.<sup>3,4</sup> Moreover, since the  $\alpha/\beta$  and recovery coefficients are selected for each optimization function (see Supplementary Figure 1 and Supplementary Figure 2), an ongoing study is exploring optimization strategies that mitigates against uncertainties in these parameters. Beyond this, the implementation also allows exploration of optimization strategies that are robust  
330 against uncertainties in delivered dose by e.g. use of an estimated worst case delivered dose in the optimization to account for uncertainties in the dose delivery, DIR, and dose mapping.

## 5. CONCLUSIONS

The proposed optimization functions introduce novel and flexible approaches for re-irradiation treatment planning which can combine EQD2- and dose-based functions without adding time in  
335 the optimization stage. The key features of the re-irradiation functions are:

- Voxelwise dose accumulation of multiple treatment courses to estimate accumulated EQD2, which is used in re-irradiation optimization based on rigid or DIR for dose mapping, with tissue specific  $\alpha/\beta$  ratios, and tissue- and treatment course specific recovery coefficients.
- 340 • An ROI-specific and voxel-specific EQD2 penalization level adjusted for the estimated previously delivered EQD2, specifying the additionally allowed EQD2 for the re-irradiation treatment.
- The option to use a uniform ROI-specific previously delivered EQD2 if the dose mapping is considered unreliable.
- 345 • Feedback on the optimized EQD2 metrics during optimization.

## CONFLICT OF INTEREST

The current work is an output from a formal research collaboration between Leeds Teaching Hospitals NHS Trust and RaySearch Laboratories AB. Kjell Eriksson is also a shareholder in  
355 RaySearch Laboratories AB.

## ACKNOWLEDGEMENT

Ane Appelt and Louise Murray are currently Associate Professors funded by Yorkshire Cancer Research (award numbers L389AA and L389LM). Authors from Leeds would also like to acknowledge Cancer Research UK funding for the Leeds Radiotherapy Research Centre of  
360 Excellence (RadNet; C19942/A28832).

Figure 2. (a): The equivalent dose in 2-Gy fraction (EQD2) distribution of the first treatment course (EQD2<sub>deliv</sub>) with the three fictitious relapse planning target volumes (PTVs) marked in black; RI (repeat irradiation), RIT1 (re-irradiation type 1) and RIT2 (re-irradiation type 2). The superimposed EQD2 distributions for the three relapse scenarios are shown for (b) reRT<sub>regular</sub>, (c) reRT<sub>reduce</sub> and (d) reRT<sub>voxelwise</sub>. The EQD2 was truncated at 14 Gy (20% iso-EQD2 line) to avoid overlap, leaving only a minor overlap of the 20% iso-EQD2 line of RI and RIT2 in (c). The contours of bladder, rectum, small bowel, and femoral heads are marked in yellow, brown, red, and blue, respectively. The EQD2 distributions were calculated using an  $\alpha/\beta = 3$  Gy for all voxels. 92% and 109% of 70 Gy EQD2 approximately corresponds to 95% and 105% of 35 Gy in 5 fractions, respectively.

440

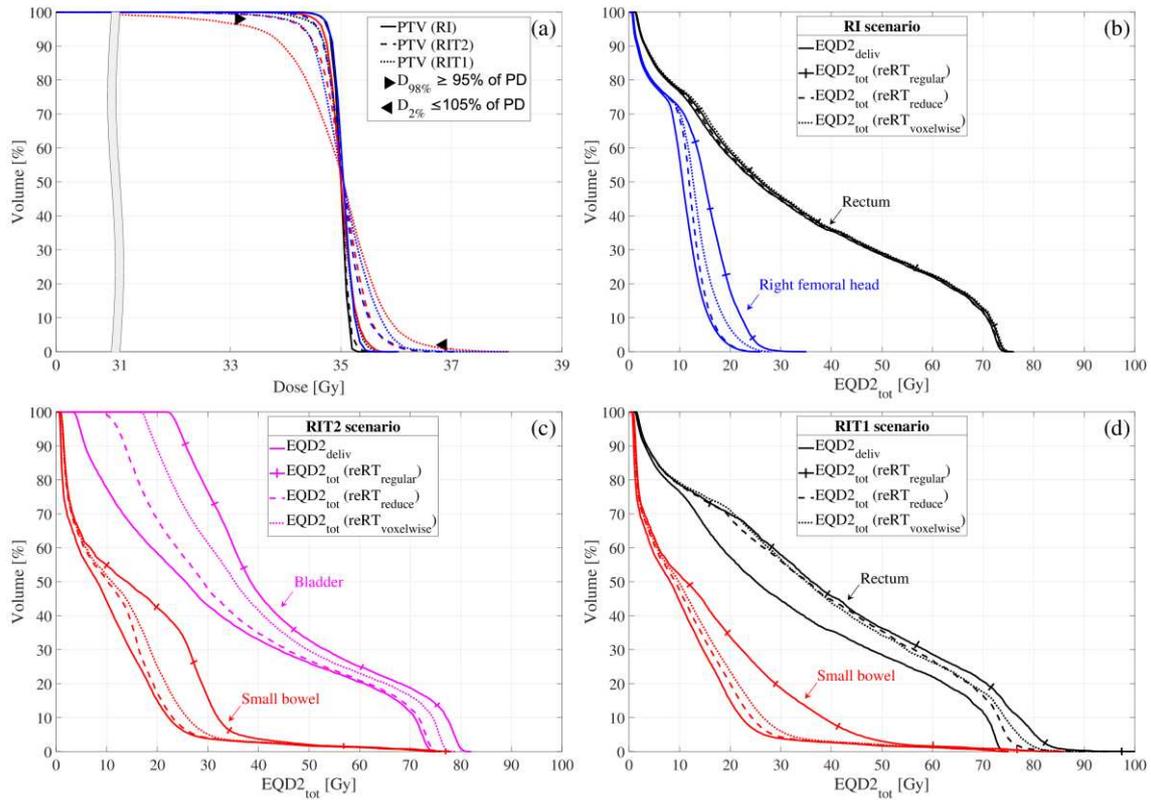

Figure 3. Dose-volume histograms (DVHs) using dose and total equivalent dose in 2-Gy fraction (EQD2<sub>tot</sub>) for the three relapse scenarios – repeat irradiation (RI), re-irradiation type 1 (RIT1) and type 2 (RIT2). (a): DVHs for the planning target volumes (PTV) with a broken x-axis for reRT<sub>regular</sub> (black lines), reRT<sub>reduce</sub> (red lines) and reRT<sub>voxelwise</sub> (blue lines) for all three relapse scenarios with the PTV coverage goals marked as horizontal black triangles. [(b), (c), and (d)]: DVHs of two organs at risk per relapse scenario for the first treatment course (EQD2<sub>deliv</sub>) in full lines and the EQD2<sub>tot</sub> for reRT<sub>regular</sub> (full lines with perpendicular crossing lines), reRT<sub>reduce</sub> (dashed lines) and reRT<sub>voxelwise</sub> (dotted lines). (b): The RI scenario, (c): the RIT2 scenario and (d): the RIT1 scenario. The EQD2 was calculated using an  $\alpha/\beta = 3$  Gy for all voxels.

Table 1. Dose evaluation metrics for the planning target volume (PTV) for all relapse scenarios and re-planning strategies.

Relapse scenario	Re-planning strategy	D <sub>98%</sub> [%]	D <sub>2%</sub> [%]	HI [%]	CI [%]
Repeat irradiation (RI)	reRT <sub>regular</sub>	99.1	100.5	1.4	92.4
	reRT <sub>reduce</sub>	98.5	101.4	2.8	93.3
	reRT <sub>voxelwise</sub>	99.0	100.9	1.9	93.0
Re-irradiation type 2 (RIT2)	reRT <sub>regular</sub>	99.1	100.8	1.7	92.8
	reRT <sub>reduce</sub>	96.8	102.6	5.8	84.1
	reRT <sub>voxelwise</sub>	98.3	102.7	4.4	93.4
Re-irradiation type 1 (RIT1)	reRT <sub>regular</sub>	98.1	101.3	3.2	94.2
	reRT <sub>reduce</sub>	92.3	104.3	12.0	73.7
	reRT <sub>voxelwise</sub>	96.9	103.0	6.1	93.7

D<sub>x%</sub> = minimum dose to x% of the PTV receiving the highest doses; CI = conformity index; HI = homogeneity index

Supplementary Figure 1. The adapted dialog in the research version of RayStation v11A for adding an optimization function. The user selects region of interest (ROI) for the function, function type, function weight, objective or constraint function, and if the function should use the beam set dose only or the accumulated dose including the estimated delivered dose. The user then selects the re-irradiation specific settings; the penalization level in equivalent dose in 2-Gy fractions ( $EQD2_{level}$ ),  $\alpha/\beta$  ratio, recovery coefficients, the minimum allowed unpenalized re-irradiation EQD2 ( $EQD2_{reRTmin}$ ), and whether to override the estimated previously delivered EQD2 ( $EQD2_{deliv}$ ) in Eq. (2) with a fixed EQD2 using one out of two options; (1) the minimum  $EQD2_{deliv}$  to the  $0.1 \text{ cm}^2$  of the ROI volume receiving the highest doses, or (2) any user-specified EQD2 value.

*Re-irradiation parameters*

Recovery coefficient(s): 0

Min reRT EQD2 level [cGy]: 500

Use near-max background dose: False

Supplementary Figure 2. Example of the optimization function lists in the research version of RayStation v11A for (a) reRT<sub>regular</sub>, (b) reRT<sub>reduce</sub> and (c) reRT<sub>voxelwise</sub> used for optimization of the type 1 re-irradiation (RIT1) scenario. The uniform target objective is dose-based, while all organs at risk (OARs) objectives use the novel re-irradiation functions acting on the total equivalent dose in 2-Gy fractions (EQD2<sub>tot</sub>). The function value (calculated using the final dose distribution) and selected function parameters from Supplementary Figure 1 are seen for each function in the list including the re-irradiation specific parameters. The  $\alpha/\beta$  ratio is shown in a separate column, while a mouse-over the corresponding ★ triggers a tooltip with the added re-irradiation function parameters as seen in (c) for the bladder maximum function. The final two columns on the right supply feedback during optimization of the corresponding EQD2 metric for the total EQD2 and the estimated previously delivered EQD2. For the maximum functions, the feedback metric is the minimum EQD2<sub>deliv</sub> to the 0.1 cm<sup>2</sup> of the ROI volume receiving the highest doses, as seen in (a), (b) and (c) while no such feedback is given for the EQD2 fall-off function.
