**Abstract:** Light-driven photoredox catalysis presents a promising approach for the activation and conversion of methane (CH<sub>4</sub>) into high value-added chemicals under ambient conditions. However, the high C–H bond dissociation energy of CH<sub>4</sub> and the absence of well-defined C–H activation sites on catalysts significantly limit the highly efficient conversion of CH<sub>4</sub> toward multicarbon (C<sub>2+</sub>) hydrocarbons, particularly ethylene (C<sub>2</sub>H<sub>4</sub>). Herein, we demonstrate a bimetallic design of Ag nanoparticles (NPs) and Pd single atoms (SAs) on ZnO for the cascade conversion of CH<sub>4</sub> into C<sub>2</sub>H<sub>4</sub> with the highest production rate compared with previous works. Mechanistic studies reveal that the synergistic effect of Ag NPs and Pd SAs, upon effecting key bond-breaking and -forming events, lowers the overall energy barrier of the activation process of both CH<sub>4</sub> and the resulting C<sub>2</sub>H<sub>6</sub>, constituting a truly synergistic catalytic system to facilitate the C<sub>2</sub>H<sub>4</sub> generation. This work offers a novel perspective on the advancement of photocatalytic directional CH<sub>4</sub> conversion toward high value-added C<sub>2+</sub> hydrocarbons through the subtle design of bimetallic cascade catalyst strategy.

## Introduction

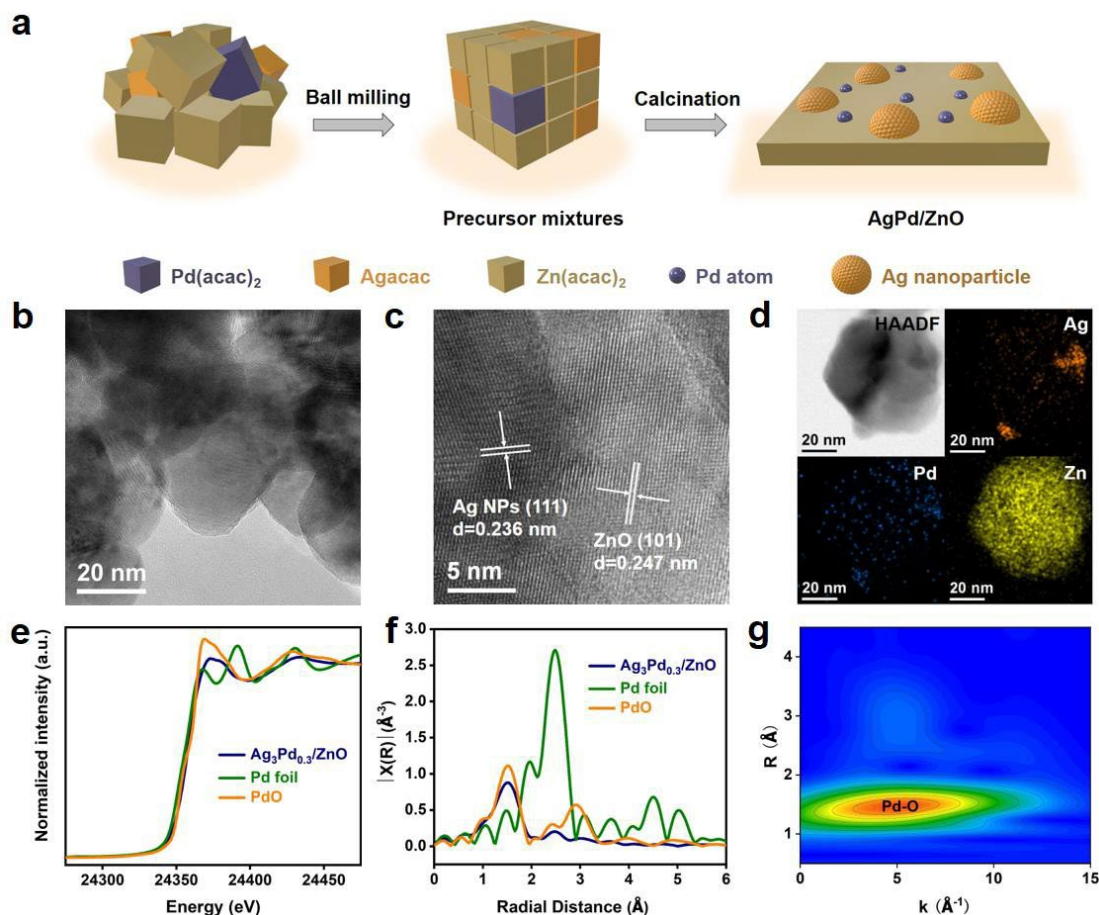

Methane (CH<sub>4</sub>), the main component of natural gas and shale gas, is considered one of the most promising chemical feedstocks due to its high abundance and relatively low cost in the context of dwindling petroleum reserves.<sup>[1]</sup> Upgrading CH<sub>4</sub> into high value-added chemicals via nonoxidative or oxidative pathways is a win-win strategy that maximizes the value of CH<sub>4</sub> for clean energy development and reduces carbon footprint.<sup>[2]</sup> Nonoxidative coupling of methane (NOCM) has emerged as an attractive approach for CH<sub>4</sub> conversion, where CH<sub>4</sub> is directly converted to multicarbon (C<sub>2+</sub>) compounds through C–H activation without any oxidant intervention, thus avoiding the overoxidation of CH<sub>4</sub> that results in undesired carbon oxides.<sup>[3]</sup> However, owing to the low polarizability and high C–H bonding energy of CH<sub>4</sub>, NOCM requires extremely high temperatures, typically leading to severe coke deposition and catalyst deactivation.<sup>[4]</sup> Under such circumstances, light-driven photoredox catalysis is seen as a prospective alternative for NOCM on account of its ability to

overcome thermodynamic limitations by providing photon energy as a driving force to enable NOCM to occur under ambient conditions.<sup>[5]</sup>

Among the products of photocatalytic NOCM, ethylene (C<sub>2</sub>H<sub>4</sub>), one of the most widely used feedstocks in the chemical industry, is of considerable importance due to its high energy content and market price. To date, however, the C<sub>2+</sub> compounds generated by photocatalytic NOCM are predominantly ethane (C<sub>2</sub>H<sub>6</sub>) rather than the more valuable C<sub>2</sub>H<sub>4</sub>.<sup>[6]</sup> From the perspective of the reaction mechanism, the conversion of CH<sub>4</sub> to C<sub>2</sub>H<sub>4</sub> is a tandem process involving the C–C coupling of CH<sub>4</sub> and the dehydrogenation of the resulting C<sub>2</sub>H<sub>6</sub> intermediate.<sup>[7]</sup> This multistep conversion includes a variety of intermediates, such as methyl (CH<sub>3</sub>) species, C<sub>2</sub>H<sub>6</sub>, ethyl (C<sub>2</sub>H<sub>5</sub>) species, to name a few,<sup>[8]</sup> whose adsorption and desorption behavior on the catalyst strongly influence the distribution of the end products. Notably, the grand challenge in the CH<sub>4</sub> conversion to C<sub>2</sub>H<sub>4</sub> is the gas-phase dehydrogenation of C<sub>2</sub>H<sub>6</sub> under mild conditions,<sup>[7a]</sup> which requires a catalyst with active sites for the simultaneous activation of both reactant CH<sub>4</sub> and intermediate C<sub>2</sub>H<sub>6</sub>. In such a scenario, synergistic catalysis is expected to be a potential strategy to overcome the current bottleneck limitation of CH<sub>4</sub>-to-C<sub>2</sub>H<sub>4</sub> transformation in view of the judicious combination of designed multifunctional active sites, spatially distributed on the catalyst surface, could sequentially promote chemical reactions that cannot be accessibly catalyzed by a single active site.<sup>[9]</sup>

Herein, we developed a facile ball milling method to co-modify Ag nanoparticles (NPs) and Pd single atoms (SAs) on ZnO (a classical catalyst support commonly used for CH<sub>4</sub> conversion) for efficient photocatalytic CH<sub>4</sub> nonoxidative conversion toward C<sub>2</sub>H<sub>4</sub> production under ambient conditions. Our methodology utilizes two synergistically working metal active sites, Ag and Pd, with complementary functions that significantly lower the overall energy barrier of the CH<sub>4</sub> conversion process while increasing catalytic activity, where each metal site plays a dominant role at different steps during the reaction. Comprehensive mechanistic studies reveal that Ag NPs are capable of facilitating the cleavage of the C–H bonds of both CH<sub>4</sub> and C<sub>2</sub>H<sub>6</sub>. Nevertheless, when CH<sub>4</sub> and C<sub>2</sub>H<sub>6</sub> coexist, single Ag sites preferentially promote C<sub>2</sub>H<sub>6</sub> activation, which is detrimental to the sustainable conversion of

$\text{CH}_4$ . In contrast, the features of Pd SAs selectively promote the C–H activation of  $\text{CH}_4$ , thus enhancing the efficiency of  $\text{CH}_4$  conversion. This work reveals the mechanism of bimetallic synergistic catalysis of  $\text{CH}_4$  conversion, providing a new reference for  $\text{CH}_4$  conversion to  $\text{C}_2\text{H}_4$  by ingeniously designing photocatalytic cascade systems with well-defined sites.

## Results and Discussion

The schematic of the overall fabrication procedure of Ag and Pd co-modified ZnO ( $\text{AgPd}/\text{ZnO}$ ) bimetallic catalysts is shown in **Figure 1a**. Specifically, corresponding metal precursors are simultaneously added to an agate jar for mechanical mixing. After calcination, the  $\text{AgPd}/\text{ZnO}$  composites are obtained, and the resulting sample is denoted as  $\text{Ag}_x\text{Pd}_y/\text{ZnO}$ , where  $x$  and  $y$  represent the mass percentage of Ag and Pd, respectively. The method is capable of precisely controlling the Pd and Ag content by adjusting the amount of Pd and Ag precursors (**Table S1**). As observed from the transmission electron microscopy (TEM) images (**Figure 1b** and **Figure S1**), Ag-derived nanoparticles (NPs) with particle size greater than 10 nm are randomly distributed on the surface of ZnO NPs. Since the catalysts are synthesized by ball milling, the morphology of Ag species and ZnO is inevitably irregular nanoparticle.<sup>[10]</sup> In addition, the formation of Pd-derived nanoparticles is not observed because

the content of Pd is too low.<sup>[11]</sup> In the obtained high-resolution transmission electron microscopy (HRTEM) images, the two well-defined lattice fringes with d-spacing of 0.236 and 0.247 nm correspond to the (111) plane of Ag NPs and the (101) crystal plane of ZnO, respectively (**Figure 1c**).<sup>[12]</sup> High-angle annular dark-field scanning TEM (HAADF-STEM) images and elemental mapping confirm the presence of Zn, O, Ag, and Pd elements in  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  (**Figure 1d**). X-ray photoelectron spectroscopy (XPS) was carried out to further analyze the chemical elemental composition and valence states of samples (**Figure S2**). The coexistence of the elements Ag, Pd, Zn and O of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  in the survey XPS spectrum is consistent with the aforementioned elemental mapping results. Furthermore, the XPS results demonstrate the existence of metallic Ag and  $\text{Pd}^{2+}$  in  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$ . The crystalline phase of samples was investigated by X-ray diffraction (XRD) as displayed in **Figure S3**. All samples exhibit the typical peaks attributed to hexagonal wurtzite ZnO (PDF#36-1451). A weak additional diffraction peak appears at  $38^\circ$  in all Ag-containing samples, which is indexed to the (111) plane of Ag NPs (PDF#04-0783).<sup>[13]</sup> However, no Pd-derived diffraction peak is observed in  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$ , probably owing to the low content or high dispersion on ZnO.<sup>[14]</sup> The light absorption property of samples was determined by ultraviolet-visible (UV/Vis) diffuse reflectance spectroscopy (DRS) in **Figure S4**. The absorption edge of pristine ZnO in the ultraviolet band is ca. 380 nm, which corresponds to the intrinsic bandgap (3.2 eV) absorption of ZnO. A significantly enhanced light absorption is observed in the visible light region after the introduction of

**Figure 2.** a) Photocatalytic CH<sub>4</sub> conversion performance of various catalysts after 4 h of illumination. b) The performance summary of the CH<sub>4</sub> nonoxidative conversion to C<sub>2</sub> compound in this work and other representative reported photocatalysts (Ga<sub>2</sub>O<sub>3</sub>-K<sup>[15]</sup>, (Zn<sup>+</sup>, Zn<sup>2+</sup>)-ZSM-5<sup>[6a]</sup>, Au/m-ZnO<sup>[6b]</sup>, Nb-TiO<sub>2</sub>-SiO<sub>2</sub><sup>[16]</sup>, Ag-HPW/TiO<sub>2</sub><sup>[17]</sup>, ZnO-AuPd<sup>[6b]</sup>, Pt/Ga<sub>2</sub>O<sub>3</sub><sup>[18]</sup>, Pd<sub>5</sub>/Zn<sub>0.35</sub>-WO<sub>3</sub><sup>[5c]</sup>, Au<sub>2</sub>-Pd<sub>2</sub>/BNOF<sup>[8]</sup>). The detailed reaction condition of these representative works is presented in **Table S3**. c) Time-dependent photocatalytic C<sub>2</sub>H<sub>6</sub> production over Ag<sub>3</sub>/ZnO, Pd<sub>0.3</sub>/ZnO and Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO. d) Time-dependent photocatalytic C<sub>2</sub>H<sub>4</sub> production over Ag<sub>3</sub>/ZnO, Pd<sub>0.3</sub>/ZnO and Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO. e) Photocatalytic C<sub>2</sub>H<sub>6</sub> conversion performance of various catalysts after 4 h of illumination. f) C<sub>2</sub> compound yields in the recycle tests of Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO (each cycle lasts 4 h).

Ag and Pd, which is due to their interband absorption or scattering.<sup>[19]</sup>

The coordination environment of Pd in Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO was further investigated by synchrotron-based X-ray absorption fine structure (XAFS) spectroscopy. The Pd K-edge XANES spectra of Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO show its threshold energy (E<sub>0</sub>) and white-line peak close to standard Pd, indicating that the electronic state of Pd in Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO is +2 (**Figure 1e**).<sup>[11]</sup> In **Figure 1f** and **g**, the extended X-ray adsorption fine structure (EXAFS) spectra of Pd K-edge in R-space and wavelet transformations of the Pd K-edge EXAFS spectra exhibit only a single-peak signal of Pd-O coordination on Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO, confirming that Pd is dispersed as isolated single atoms and coordinated with O atoms in the Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO.<sup>[20]</sup> The quantitative coordination configuration of individual Pd atoms is derived based on EXAFS curve fitting, and the average coordination number (CN) of Pd-O in Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO is determined to be 4 ± 0.2 (**Figure S5** and **Table S2**).<sup>[21]</sup>

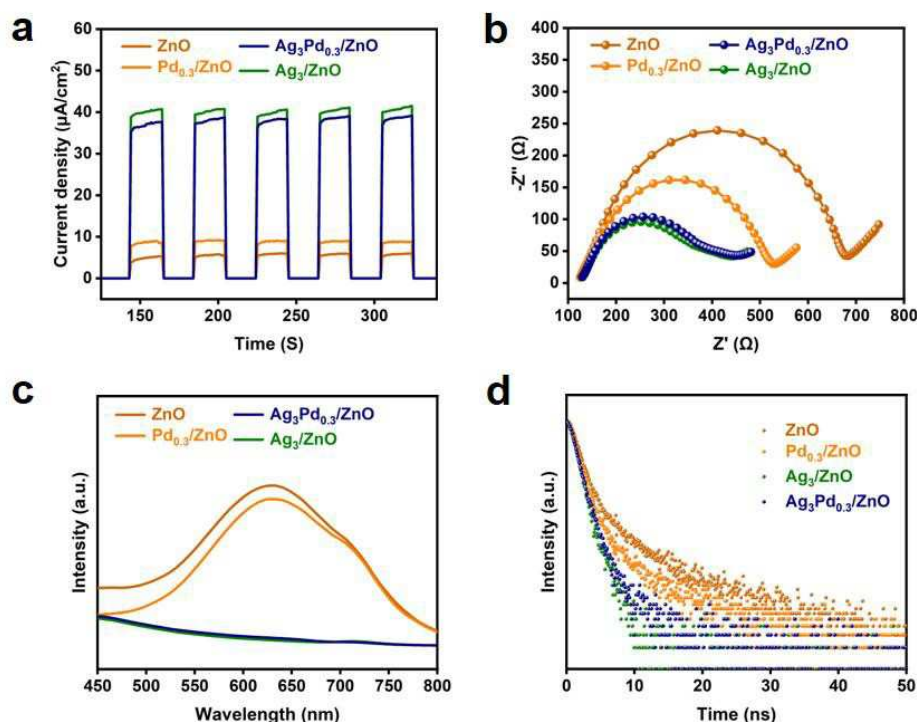

Upon confirming the structural information of the prepared samples, we evaluated their performance for photocatalytic CH<sub>4</sub> conversion in the gas-solid phase (1 mL CH<sub>4</sub> in argon (Ar), 1 atm pressure) under Xe lamp illumination. As displayed in **Figure 2a**, no C<sub>2</sub> compounds are detected over pristine ZnO. After the modification of Ag, the yield of C<sub>2</sub> compounds was significantly improved (**Figure S6**). In particular, the optimized Ag<sub>3</sub>/ZnO shows excellent photocatalytic CH<sub>4</sub> conversion performance (376 μmol g<sup>-1</sup> of C<sub>2</sub>H<sub>6</sub> and 90.8 μmol g<sup>-1</sup> of C<sub>2</sub>H<sub>4</sub> after 4 h of light irradiation). Considering the feature of Pd in the breakage of the C-H bond of CH<sub>4</sub>,<sup>[22]</sup> Pd was introduced into Ag<sub>3</sub>/ZnO to further enhance the

CH<sub>4</sub> conversion performance (**Figure S7**). After optimizing the Pd loading amount, Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO exhibits the optimal catalytic performance (515 μmol g<sup>-1</sup> of C<sub>2</sub> compounds with C<sub>2</sub>H<sub>4</sub> selectivity of 39% under 4 h of illumination), which is superior to most of the recent works on CH<sub>4</sub> conversion to C<sub>2</sub> compounds (**Figure 2b** and **Table S3**). The C<sub>2</sub>H<sub>4</sub> yield of Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO is more than double that of Ag<sub>3</sub>/ZnO, whereas only a small amount of C<sub>2</sub>H<sub>6</sub> is detected on Pd<sub>0.3</sub>/ZnO during the same reaction time. These results clearly demonstrate the importance of the synergistic effect of Ag and Pd in promoting the conversion of CH<sub>4</sub> to C<sub>2</sub>H<sub>4</sub>.

A series of blank experiments have been carried out, which show that no C<sub>2</sub> products could be detected in the absence of photocatalyst, under dark conditions, or without CH<sub>4</sub>, demonstrating that this is a photocatalytic process and CH<sub>4</sub> is the only carbon source (**Figure S8a**). Isotopic labeling tests using <sup>13</sup>CH<sub>4</sub> as the feedstock further confirm the origin of the resulting C<sub>2</sub>H<sub>4</sub> and C<sub>2</sub>H<sub>6</sub>. As shown in **Figure S8b**, dominant peaks attributed to <sup>13</sup>C<sub>2</sub>H<sub>4</sub> and <sup>13</sup>C<sub>2</sub>H<sub>6</sub> and their molecular fragments can be observed, such as <sup>13</sup>C<sub>2</sub>H<sub>4</sub> (m/z=30, 29, 28) and <sup>13</sup>C<sub>2</sub>H<sub>6</sub> (m/z=32, 31, 30, 29, 28), respectively.<sup>[14]</sup> These results collectively indicate that the generated C<sub>2</sub> compounds undoubtedly originate from the feedstock CH<sub>4</sub>.

To evaluate the long-term stability of the photocatalysts, we further performed time-dependent measurements with continuous light irradiation for 12 h over prepared samples. As shown in **Figure S9**, the C<sub>2</sub>H<sub>6</sub> yield of Ag<sub>3</sub>Pd<sub>0.3</sub>/ZnO gradually increases and then becomes steady along with the duration of illumination time, while the yield and selectivity of C<sub>2</sub>H<sub>4</sub> enhance continuously.

**Figure 3.** a) Transient photocurrent spectra, b) EIS spectra, c) steady-state PL emission spectra and d) TRPL spectra of various catalysts.

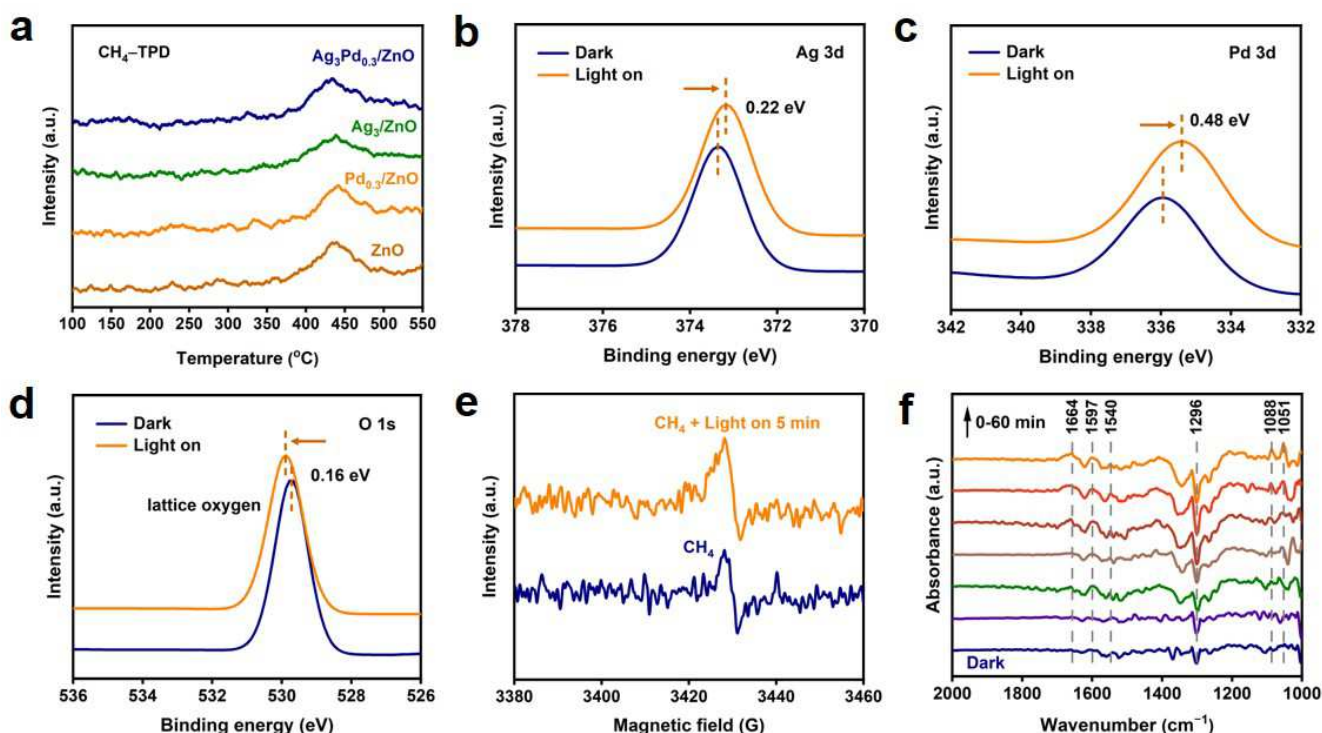

Specifically,  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  achieves a yield of  $682 \mu\text{mol g}^{-1}$  of the  $\text{C}_2$  compounds after 12 h of reaction (47% selectivity for  $\text{C}_2\text{H}_4$ ). Interestingly, in the case of  $\text{Ag}_3/\text{ZnO}$ , the generated  $\text{C}_2\text{H}_6$  is consumed with the extension of reaction time and at a rate comparable to the rate of increase of  $\text{C}_2\text{H}_4$  (Figure 2c and d), implying that  $\text{C}_2\text{H}_4$  is converted from the generated  $\text{C}_2\text{H}_6$ . This illustrates that Ag NPs not only facilitate the C–H activation of  $\text{CH}_4$ , but also supply active sites for the conversion of  $\text{C}_2\text{H}_6$  to  $\text{C}_2\text{H}_4$ . On the other hand, Ag NPs alone preferentially accelerate the activation of  $\text{C}_2\text{H}_6$  when  $\text{CH}_4$  and  $\text{C}_2\text{H}_6$  coexist, which is detrimental to the sustainable conversion of  $\text{CH}_4$ , also demonstrating the limited functionality of a single active site. Apparently, the features of Pd SAs in promoting the  $\text{CH}_4$  activation compensate for this drawback in our system. Besides, we also implement comparative experiments using  $\text{C}_2\text{H}_6$  as feedstock (Figure 2e, 1 mL  $\text{C}_2\text{H}_6$  in Ar, 1 atm pressure). As expected, both  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  and  $\text{Ag}_3/\text{ZnO}$  lead to superior  $\text{C}_2\text{H}_6$  conversion performance ( $2500 \mu\text{mol g}^{-1}$  of  $\text{C}_2\text{H}_4$  with  $\text{C}_2\text{H}_4$  selectivity of  $\sim 100\%$  under 4 h of illumination). In contrast,  $\text{C}_2\text{H}_4$  production on pristine ZnO and  $\text{Pd}_{0.3}/\text{ZnO}$  is almost negligible, further demonstrating the excellent performance of Ag NPs for the efficient and selective conversion of  $\text{C}_2\text{H}_6$  to  $\text{C}_2\text{H}_4$ . It should be noted that the stoichiometric mismatch between the  $\text{H}_2$  evolution and the yield of  $\text{C}_2$  compounds is closely related to the consumption of lattice oxygen in ZnO during the reaction (Figure S10).<sup>[5b, 23]</sup> The lattice oxygen consumed in ZnO can be regenerated by heating the catalyst in air to restore its catalytic activity. Durability measurements show that  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  maintains good catalytic performance during six cycling tests, with each cycle lasting 4 h (Figure 2f). Additionally, the leaching of Ag and Pd during the cycling test is negligible according to the ICP-

AES results (Table S4). As such, a durable photochemical  $\text{CH}_4$  conversion can be achieved by recovering and reusing the catalyst.

Photoelectrochemical and photoluminescence (PL) characterization were further performed to reveal the effect of photogenerated charge separation/transfer on photocatalytic  $\text{CH}_4$  conversion performance.<sup>[24]</sup> The transient photocurrent response and electrochemical impedance spectroscopy (EIS) spectra show that the modification of Ag significantly improves the photogenerated charge separation efficiency (Figure 3a and b). However, the similar photoelectrochemical properties of  $\text{Ag}_3/\text{ZnO}$  and  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  indicate that the introduction of Pd SAs does not further promote charge separation efficiency. As presented in Figure 3c and d, PL and time-resolved PL (TRPL) characterization results also show a similar tendency, implying that the effect of Pd SAs on the suppression of electron-hole pairs recombination is extremely limited compared to Ag NPs (Table S5). The inconsistency between the photoelectric efficiency and photocatalytic performance for  $\text{CH}_4$  conversion implies that the separation and transfer of photogenerated charge carriers are not the dominant factors affecting the  $\text{C}_2\text{H}_4$  production in our system.

It is well known that the photocatalytic  $\text{CH}_4$  conversion process involves light absorption, photogenerated charge carrier separation/transfer, and interaction between the catalyst active sites and the  $\text{CH}_4$  molecule.<sup>[1d, 25]</sup> The above characterization results indicate that the former two stages do not have a decisive influence on  $\text{C}_2\text{H}_4$  production. In order to gain insight into the functional orientation of catalyst surface sites during  $\text{CH}_4$  conversion, the  $\text{CH}_4$  adsorption experiment on the samples was first performed by  $\text{CH}_4$  temperature-programmed-desorption (TPD) analysis. As shown in Figure 4a, the desorption peak at

**Figure 4.** a)  $\text{CH}_4$ -TPD profiles of various catalysts. b) In situ Ag 3d XPS spectra of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  under the dark condition and light irradiation. c) In situ Pd 3d XPS spectra of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  under the dark condition and light irradiation. d) In situ O 1s XPS spectra of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  under the dark condition and light irradiation. e) In situ EPR signals of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  collected in  $\text{CH}_4$  atmosphere. f) In situ DRIFTS spectra for photocatalytic conversion of  $\text{CH}_4$  over  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$ .

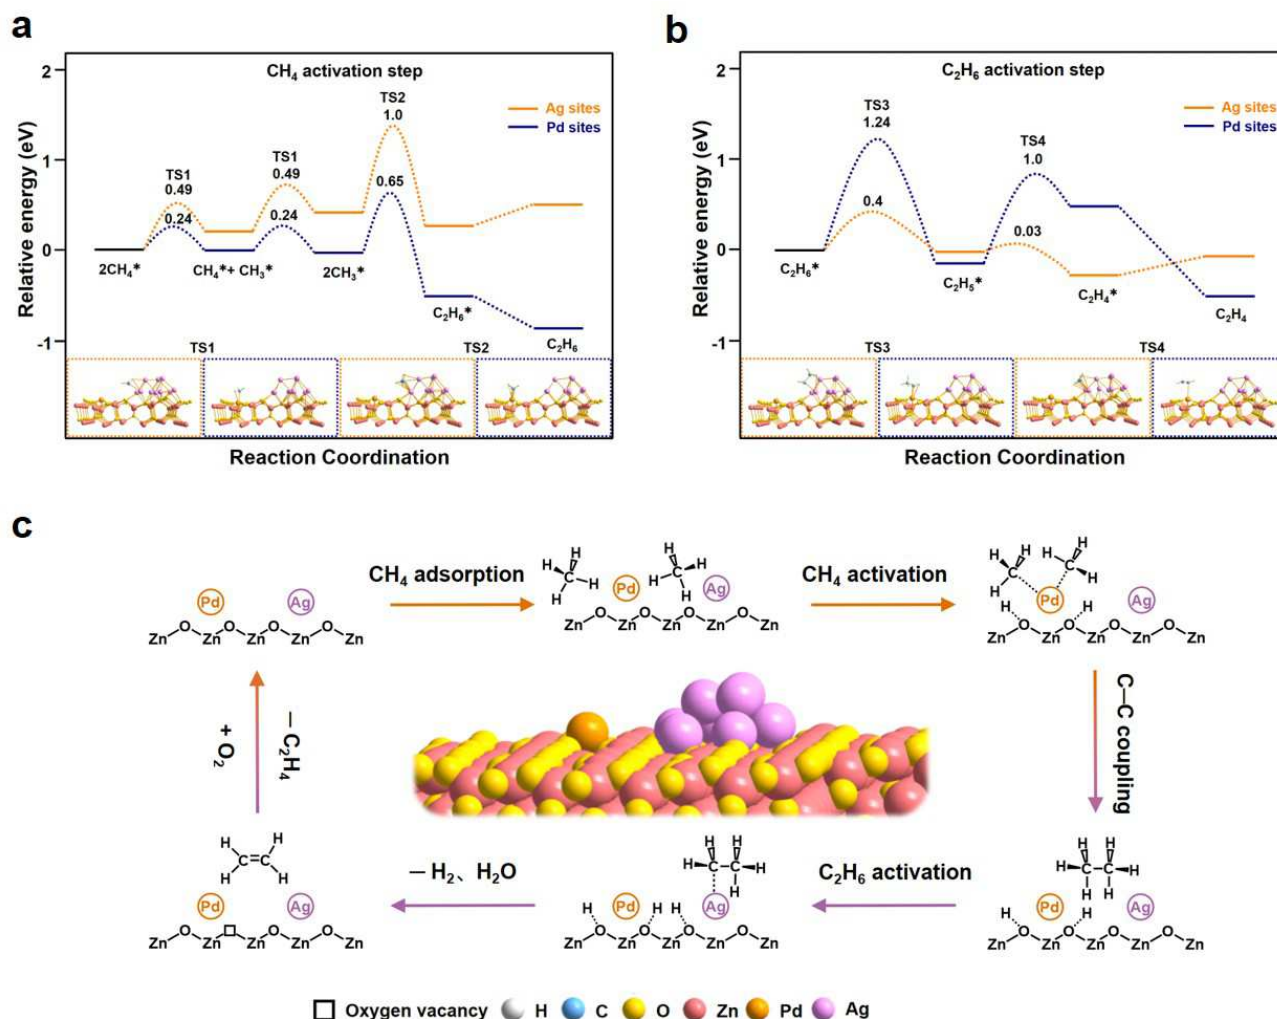

around 440  $^\circ\text{C}$  is attributed to the strong adsorption of  $\text{CH}_4$  on the catalyst surface.<sup>[26]</sup> The modification of Ag and Pd hardly affects the adsorption behavior of  $\text{CH}_4$  on ZnO surface. In situ XPS was performed to further explore the carrier transfer behavior (**Figure 4b-d** and **Figure S11**). During light irradiation, a negative shift of  $\sim 0.22$  eV of the Ag 3d peak can be clearly observed, suggesting that Ag works as an electron acceptor during the reaction. However, it is difficult to recognize the clear signal of Pd 3d of  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  due to the low weight content. Therefore,  $\text{Ag}_3\text{Pd}_1/\text{ZnO}$  with higher Pd content prepared under the same conditions was used to investigate the function of Pd. The negative shift of  $\sim 0.48$  eV of Pd 3d peak under illumination implies that Pd also acts as an electron acceptor in the reaction. In parallel, O 1s peak exhibits a positive shift of 0.16 eV, indicating that holes are aggregated at the oxygen sites of ZnO for  $\text{CH}_4$  activation.<sup>[27]</sup> In situ electron paramagnetic resonance (EPR) measurements for the oxygen vacancies of the samples further support this conclusion (**Figure 4e** and **Figure S12a**). The signal intensity of oxygen vacancies on  $\text{Ag}_3\text{Pd}_{0.3}/\text{ZnO}$  is enhanced under the  $\text{CH}_4$  atmosphere upon illumination, whereas no significant signal change is observed on pristine ZnO, demonstrating that the lattice oxygen sites enriched by photogenerated holes are consumed during the reaction.

In situ Fourier transform infrared spectroscopy (FT-IR) method was employed to further detect  $\text{CH}_4$  intermediates during the reaction. In **Figure 4f**, a new peak around 1540  $\text{cm}^{-1}$  attributed to the C-H symmetry vibration of adsorbed  $\text{CH}_4$  and the decrease of the peak around 1296  $\text{cm}^{-1}$  belonging to free  $\text{CH}_4$  molecules

collectively demonstrate the photoenhanced  $\text{CH}_4$  adsorption, which is induced by the photogenerated  $\text{Zn}^+-\text{O}^-$  pairs on the ZnO surface.<sup>[28]</sup> Simultaneously, the peak at 1664  $\text{cm}^{-1}$  is assigned to the surface-adsorbed hydroxyl species associated with the surface lattice oxygen of ZnO adsorbing the cleaved H atoms extracted from  $\text{CH}_4$ .<sup>[29]</sup> Furthermore, the peak around 1597  $\text{cm}^{-1}$  is ascribed to the bending vibration of the O-H bond of  $\text{H}_2\text{O}$  molecules,<sup>[30]</sup> suggesting that  $\text{H}_2\text{O}$  is generated during the  $\text{CH}_4$  conversion reaction, which is the destination of the lattice oxygen consumed in ZnO and the H atoms adsorbed on these lattice oxygen as mentioned in the previous section. Notably, the peaks located at 1051  $\text{cm}^{-1}$  and 1088  $\text{cm}^{-1}$  are attributed to the surface-adsorbed ethyl ( $\text{C}_2\text{H}_5^*$ ) and methyl ( $\text{CH}_3^*$ ) species, which are key intermediates for the formation of  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_6$ , respectively.<sup>[5b, 8]</sup> In sharp contrast, the signals of these  $\text{CH}_4$ -derived intermediates are not detected on ZnO (**Figure S13a**), meaning that the  $\text{CH}_4$  to  $\text{C}_2\text{H}_4$  conversion reaction cannot proceed without Ag NPs and Pd SAs although the photogenerated  $\text{Zn}^+-\text{O}^-$  sites on substrate ZnO can trigger  $\text{CH}_4$  activation. Taken together, the interactions between  $\text{CH}_4$ -derived intermediates and metal sites (Ag NPs and Pd SAs) are significant for  $\text{CH}_4$  conversion.

To gain insights into the nature of the active sites on the catalyst surface for the conversion of  $\text{CH}_4$  to  $\text{C}_2\text{H}_4$ , density-functional theory (DFT) calculations of the reaction mechanism were performed. Two models are built and optimized to simulate the structures of pristine ZnO and  $\text{AgPd}/\text{ZnO}$  (**Figure S14**). As depicted in **Figure S15**, the first deprotonation step of  $\text{CH}_4$  over pristine ZnO is endergonic by the activation energy of 0.72 eV,

## RESEARCH ARTICLE

**Figure 5.** Calculated potential energy diagrams for a) the CH<sub>4</sub> activation step and b) the C<sub>2</sub>H<sub>6</sub> intermediate activation step in the CH<sub>4</sub> conversion to C<sub>2</sub>H<sub>4</sub> at Ag sites and Pd sites on AgPd/ZnO. c) Schematic illustration for photocatalytic CH<sub>4</sub> nonoxidative conversion toward C<sub>2</sub>H<sub>4</sub> over AgPd/ZnO. Insets: atomic configurations of the reaction intermediates.

dissociating into CH<sub>3</sub><sup>\*</sup>. Due to the high energy barrier (5.7 eV), the thermodynamic infeasibility of the C–C coupling of CH<sub>3</sub><sup>\*</sup> hinders the progress of the reaction. Such a high energy barrier of C–C coupling is attributed to the strong adsorption of CH<sub>3</sub><sup>\*</sup> on the lattice oxygen of ZnO (–3.27 eV, **Table S6**). In **Figure 5a**, with the introduction of Ag NPs and Pd SAs, the C–H dissociation energy of CH<sub>4</sub> is significantly decreased to an energy barrier of 0.49 eV and 0.24 eV, respectively, thus effectively promoting the C–H bond activation of CH<sub>4</sub>. Thereafter, the C–C coupling of CH<sub>3</sub><sup>\*</sup> over Ag and Pd sites only requires overcoming energy barriers of 1 eV and 0.65 eV, respectively. Obviously, Ag NPs and Pd SAs are more conducive to the generation of C<sub>2</sub>H<sub>6</sub> owing to the weak interaction between CH<sub>3</sub><sup>\*</sup> and the metal sites (0.36 eV at Ag sites and –0.06 eV at Pd sites, **Table S7**). As the reaction further proceeded, the generated C<sub>2</sub>H<sub>6</sub> undergoes another dehydrogenation process to form C<sub>2</sub>H<sub>4</sub> (**Figure 5b**). Similar to the activation process of CH<sub>4</sub>, Ag sites accelerate the deprotonation of C<sub>2</sub>H<sub>6</sub> by overcoming a moderate energy barrier of 0.4 eV to form C<sub>2</sub>H<sub>5</sub><sup>\*</sup>, which is subsequently dehydrogenated to C<sub>2</sub>H<sub>4</sub>. Notably, DFT calculations show that Ag sites are more thermodynamically capable of promoting C<sub>2</sub>H<sub>6</sub> activation than

CH<sub>4</sub> activation, consistent with the experimental results. In contrast, the C<sub>2</sub>H<sub>6</sub> activation is significantly harder thermodynamically at the Pd sites due to the high energy barrier of 1.24 eV. As a consequence of this as well as the low desorption energy of C<sub>2</sub>H<sub>6</sub> at the Pd sites (–0.35 eV, **Table S7**), the C<sub>2</sub>H<sub>6</sub> generated at the Pd sites is desorbed into the gas phase followed by adsorption and dehydrogenation at the Ag sites.

Based on the above experimental and theoretical results, the overall catalytic reaction mechanism is proposed (**Figure 5c**). Initially, photogenerated charge carriers are generated on ZnO upon light illumination. The photogenerated holes enriched in the lattice oxygen sites of ZnO, activating the C–H bond cleavage of CH<sub>4</sub> to form CH<sub>3</sub><sup>\*</sup>. Subsequently, C–C coupling of CH<sub>3</sub><sup>\*</sup> occurs on Pd SAs to generate C<sub>2</sub>H<sub>6</sub>. Finally, the generated C<sub>2</sub>H<sub>6</sub> deprotonates to C<sub>2</sub>H<sub>5</sub><sup>\*</sup>, which migrates to the Ag sites for dehydrogenation to C<sub>2</sub>H<sub>4</sub>. Meanwhile, some of the H atoms extracted from CH<sub>4</sub> are reduced to H<sub>2</sub> by photogenerated electrons, and the remaining H atoms combine with the lattice oxygen of ZnO to form H<sub>2</sub>O.

## RESEARCH ARTICLE

## Conclusion

In summary, we present a bimetallic synergistic catalytic strategy for the cascade photocatalytic CH<sub>4</sub> conversion to C<sub>2</sub>H<sub>4</sub> over ZnO co-modified with Ag NPs and Pd SAs. Our system demonstrates superior performance in photocatalytic nonoxidative coupling of CH<sub>4</sub> to C<sub>2</sub>H<sub>4</sub>, providing a high CH<sub>4</sub> conversion of 1.4 mmol g<sup>-1</sup> with a high C<sub>2</sub>H<sub>4</sub> selectivity of nearly 50% after 12 h of illumination, which is greatly superior to most of the recent works on NOCM. Mechanistic studies show that Ag NPs and Pd SAs on ZnO acting as electron acceptors during the reaction effectively promote the separation/transfer of photogenerated charge carriers. More importantly, Pd SAs and Ag NPs synergistically contribute to the generation of C<sub>2</sub>H<sub>4</sub> by promoting the C–H activation of both CH<sub>4</sub> and the resulting C<sub>2</sub>H<sub>6</sub>, respectively. This work highlights the key importance of the sensible design of well-defined catalyst with functionally complementary multiple active sites as an appealing strategy for the sustainable and directional conversion of CH<sub>4</sub> to high value-added hydrocarbons.

## RESEARCH ARTICLE

## Entry for the Table of Contents

We present a bimetallic design of Ag nanoparticles (NPs) and Pd single atoms (SAs) on ZnO for the cascade photocatalytic  $\text{CH}_4$  conversion toward  $\text{C}_2\text{H}_4$  with the highest production rate compared with previous works. The synergistic effect of Ag NPs and Pd SAs lowers the overall energy barrier of the activation process of both  $\text{CH}_4$  and the resulting  $\text{C}_2\text{H}_6$ , constituting a truly synergistic catalytic system to facilitate the  $\text{C}_2\text{H}_4$  generation.
