 (Received 26 June 2024; revised 29 September 2024; accepted 21 October 2024; published 20 November 2024)

Measuring deeply virtual Compton scattering (DVCS) on the neutron is one of the necessary steps to understand the structure of the nucleon in terms of generalized parton distributions (GPDs). Neutron targets play a complementary role to transversely polarized proton targets in the determination of the GPD E . This poorly known and poorly constrained GPD is essential to obtain the contribution of the quarks' angular momentum to the spin of the nucleon. DVCS on the neutron was measured for the first time selecting the exclusive final state by detecting the neutron, using the Jefferson Lab longitudinally polarized electron beam, with energies up to 10.6 GeV, and the CLAS12 detector. The extracted beam-spin asymmetries, combined with DVCS observables measured on the proton, allow a clean quark-flavor separation of the imaginary parts of the Compton form factors \mathcal{H} and \mathcal{E} .

DOI: [10.1103/PhysRevLett.133.211903](https://doi.org/10.1103/PhysRevLett.133.211903)

Understanding the structure of the nucleon in terms of quarks and gluons, collectively called partons, is one of the main challenges of hadronic physics. The formalism of generalized parton distributions (GPDs) [1–8] provides a universal description of the partonic structure of the nucleon. GPDs correlate partons in different quantum states, and can be interpreted as the spatial distributions in the transverse plane of partons carrying a given longitudinal momentum fraction. The simultaneous knowledge of longitudinal momentum and transverse position gives

access to the angular momentum of quarks and gluons [2,3]. Therefore, the determination of GPDs can clarify the so-called “spin crisis” that ensued from the measurements [9] showing that the spins of the quarks contribute to only 20%–30% of the nucleon's spin.

GPDs derive from the theory of the strong interaction, quantum chromodynamics (QCD), as they are the Fourier transforms of nonlocal and nondiagonal QCD operators. They are most easily accessed in the measurement of the exclusive lepton production of a photon (deeply virtual Compton scattering, or DVCS) or a meson on the nucleon, at sufficiently large Q^2 , which is the virtuality of the photon emitted by the initial lepton [$Q^2 = -(k - k')^2$, where k and k' are the momenta of the initial and final state leptons, respectively]. Figure 1 illustrates the leading-order diagram for DVCS, where QCD factorization is applied, splitting the process into the hard quark-photon scattering part, calculable in perturbative quantum electrodynamics, and the soft nucleon-structure part. Considering only helicity-conserving processes and the quark sector, the soft structure of the nucleon is parametrized by four GPDs for each quark flavor: $H, \tilde{H}, E, \tilde{E}$ (the tilde denotes polarized GPDs),

FIG. 1. The “handbag” diagram for the DVCS process on the nucleon $eN \rightarrow e'N'\gamma$. The four-vectors of the incoming and outgoing electrons, photons, and nucleons are denoted by k/k' , q/q' , and p/p' , respectively. $t = (p - p')^2$ and ξ is proportional to the Bjorken variable x_B ($\xi \simeq [x_B/(2 - x_B)]$, where $x_B = (Q^2/2M\nu)$, M is the nucleon mass, and $\nu = E_e - E_{e'}$).

which depend, in leading-order and leading-twist QCD, upon three variables: x , ξ , and t . x , the average parton momentum fraction, is not accessible experimentally in the DVCS process. $x + \xi$ and $x - \xi$ are the longitudinal momentum fractions of the quarks, respectively, coming out from and going back into the nucleon. t is the squared four-momentum transfer between the final and initial state nucleons. Figure 1 and its caption illustrate the definitions of the relevant variables.

DVCS shares the same final state with the Bethe-Heitler (BH) process, where a real photon is emitted by either the incoming or the scattered electron. At the cross-section level BH is typically larger than DVCS, but information on the latter can be obtained by extracting the DVCS-BH interference term, and exploiting the fact that the amplitude from BH can be computed. Spin-dependent asymmetries, which at leading-twist depend mainly on the interference term, can then be connected to linear combinations of real and imaginary parts of Compton form factors (CFFs, $\mathcal{F} = \{\mathcal{H}, \mathcal{E}, \tilde{\mathcal{H}}, \tilde{\mathcal{E}}\}$), defined for a generic GPD F ($F = \{H, E, \tilde{H}, \tilde{E}\}$) as

$$\Re\mathcal{F} = \mathcal{P} \int_0^1 dx \left[\frac{1}{x - \xi} \pm \frac{1}{x + \xi} \right] [F(x, \xi, t) \mp F(-x, \xi, t)] \quad (1)$$

$$\Im\mathcal{F} = F(\xi, \xi, t) \mp F(-\xi, \xi, t), \quad (2)$$

where \mathcal{P} is the principal value of the integral, and the top and bottom signs apply, respectively, to the unpolarized

GPDs (H, E) and to the polarized GPDs (\tilde{H}, \tilde{E}). Measuring GPDs is a complex task, calling for a long-term experimental program comprising the measurement of different observables [8,10]. Such a dedicated experimental program, mainly focused on a proton target, has been carried out worldwide, in particular at Jefferson Lab, with CLAS/CLAS12 and Hall A [11–20], and at HERA with HERMES [21–27], H1 [28–30], and Zeus [31,32] and at CERN with COMPASS [33], bringing strong constraints to the GPD H and indications on the size and kinematic dependence of \tilde{H} .

Measuring DVCS on both protons and neutrons is essential to carry out the quark-flavor separation of GPDs. Moreover, the beam-spin asymmetry (BSA, hereafter also denoted by A_{LU} where L indicates the longitudinally polarized beam and U the unpolarized target) for DVCS on the neutron is strongly sensitive to the GPD E , which is poorly known and constrained. E is of particular interest as it enters, along with H , in Ji’s sum rule [2,3]

$$\sum_q \int_{-1}^{+1} dx x [H^q(x, \xi, t=0) + E^q(x, \xi, t=0)] = 2J_q, \quad (3)$$

which links the total angular momentum J_q carried by each quark q to the sum of the second moments over x of the GPDs H and E . In a first approximation, the BSA relates to the CFFs as [34]

$$A_{LU} \propto \sin\phi \Im [F_1 \mathcal{H} + \xi(F_1 + F_2) \tilde{\mathcal{H}} + kF_2 \mathcal{E}], \quad (4)$$

where ϕ is the angle between the lepton scattering and photon production planes, F_1 and F_2 are the Dirac and Pauli form factors, and $k = -t/4M^2$ with M the nucleon’s mass. Because of the different values of F_1 and F_2 for the proton and neutron, and to the small size of ξ , the BSA will be mainly sensitive to $\Im\mathcal{H}$ of the proton, if the target is a proton, and to $\Im\mathcal{E}$ of the neutron, if the target is a neutron.

The importance of neutron targets in the DVCS phenomenology was established by a pioneering Hall A experiment [35] that was then repeated with higher statistics [36]. Both experiments measured polarized-beam cross-section differences for DVCS off a neutron from a deuterium target by detecting the scattered electron and the DVCS or BH photon [$ed \rightarrow e'\gamma(np, d)$] and then subtracting data taken, in the same detection topology, on a hydrogen target [$ep \rightarrow e'\gamma(p)$].

This Letter presents results for the BSA of neutron-DVCS (nDVCS) from a deuterium target, $ed \rightarrow e'n\gamma(p)$. This is the first nDVCS measurement with detection of the recoil neutron.

The experiment ran at Jefferson Lab in Hall B, using the large acceptance spectrometer CLAS12 [37] and the longitudinally polarized electron beam produced by the Continuous Electron Beam Accelerator Facility. An average beam polarization of $\sim 85\%$ was measured throughout the experiment using a Møller polarimeter. The 5-cm-long

target was filled with unpolarized liquid deuterium. The experiment ran between February 2019 and January 2020 during three periods, collecting an integrated luminosity of roughly 285 fb^{-1} . A quarter of the data was taken at a beam energy of 10.6 GeV, another quarter at 10.2 GeV, and half at 10.4 GeV. Events with at least one electron, one photon, and one neutron were selected for the DVCS analysis. The electrons emitted at polar angles $7^\circ \lesssim \theta_e \lesssim 36^\circ$ were identified combining signals from the high-threshold Cherenkov counter [38] and the electromagnetic calorimeters (ECALs) [39], and their kinematics were measured by the drift chambers [40]. The photons were identified and reconstructed by two electromagnetic calorimeters: the ECAL for $5^\circ \lesssim \theta_\gamma \lesssim 35^\circ$ and the Forward Tagger [41] for $2.5^\circ \lesssim \theta_\gamma \lesssim 4.5^\circ$. The neutrons were identified and their kinematics reconstructed either by the ECAL or by the Central Neutron Detector [42], conceived specifically for this experiment, and the Central Time of Flight [43].

In the case where multiple final-state particles of the same type were detected in an event, all possible combinations were examined. The chosen combination was the one minimizing a χ^2 -like quantity calculated using variables related to the exclusive final state.

To determine the selection criteria for the exclusivity, a GEANT-4 Monte Carlo simulation of CLAS12 was used [44]. An event generator for incoherent electroproduction of photons on deuterium was adopted, which produces either $ed \rightarrow e'n\gamma(p)$ or $ed \rightarrow e'p\gamma(n)$ events, proportionally to their relative cross sections, coming from the nDVCS or proton-DVCS (pDVCS) and BH reactions [45]. The DVCS amplitude is calculated according to the Belitsky-Muller-Kirchner formalism [46]. The Fermi-motion distribution is implemented via the Paris potential [47].

Several cuts were applied in order to ensure proper particle identification and select the relevant kinematic region for the DVCS reaction. Fiducial cuts were applied to remove the edges of the detector. The electron momentum was required to be above 1 GeV. Only neutrons with momenta above 0.35 GeV were kept, in order to remove spectator-neutron events. The minimum photon energy was required to be 2 GeV. The cone angles formed by the electron and the neutrals, the photon or the neutron ($\theta_{e\gamma}$, θ_{en}), were required to be bigger than 5° to remove radiative photons produced by the electrons while passing through the target and detector materials, as well as those erroneously reconstructed neutral clusters identified as photons or neutrons while being part of the electron shower in the calorimeter. Imposing $Q^2 > 1 \text{ GeV}^2$ and $W > 2 \text{ GeV}$ ensured the applicability of the leading-twist GPD formalism and minimized contributions from nucleon resonances.

Exclusivity cuts were applied to select the $e'n\gamma(p)$ final state while minimizing the background coming from partially reconstructed π^0 decays from the $ed \rightarrow e'n\pi^0(p)$ reaction, where only one of the two photons from the π^0 decay was reconstructed and the

event passed the DVCS selection cuts. Cuts on the missing masses of X in the $en \rightarrow e'n\gamma X$ and $en \rightarrow e'nX$ reactions, and on the missing momentum of X in $ed \rightarrow e'n\gamma X$ were imposed [$|MM_X^2(en \rightarrow e'n\gamma X)| < 0.1 \text{ GeV}^2$, $|MM_X^2(en \rightarrow e'nX)| < 2.5 \text{ GeV}^2$, $P_X(ed \rightarrow e'n\gamma X) < 0.35 \text{ GeV}$]. A further cut was imposed on $\Delta\phi$ ($-1.5^\circ < \Delta\phi < 0.75^\circ$), the difference between the two ways of computing the angle ϕ between the leptonic and hadronic planes (using the nucleon and the virtual photon and using the virtual and the real photon). A similar cut was applied on Δt ($|\Delta t| < 0.5 \text{ GeV}^2$) the difference between the two ways to compute t , using either the scattered nucleon or the virtual and real photon. Finally, a cut on $\theta_{\gamma X}$, the cone angle between the detected γ and the missing particle X in $en \rightarrow e'n'X$, was applied ($\theta_{\gamma X} < 3^\circ$). Figure 2 shows the squared missing mass of X in $ed \rightarrow e'n\gamma X$ and the missing momentum P_X for the data and the simulations for DVCS and for π^0 , after having applied the exclusivity cuts. The data still contain some background from partially reconstructed π^0 decays.

Because of inefficiencies in the Central Tracker [48], some protons were misidentified as neutrons. This background was reduced using a multivariate analysis technique (boosted decision tree) [49] that relied on low-level features from the Central Neutron Detector and the Central Time of Flight, and on $\Delta\phi$. The remaining contamination from protons to the neutron sample was estimated to be $\sim 5\%$ and subtracted in the computation of the BSA. Overall, 77 580 events remained after all selections were applied. Figure 3 shows the kinematic coverage in Q^2 and x_B of the selected events.

The π^0 contamination to the DVCS sample was evaluated and subtracted [50]. First, the ratio, from simulations, of partially reconstructed $e'n\pi^0(1\gamma)$ events passing the

FIG. 2. Squared missing mass (left) and missing momentum (right) from $ed \rightarrow e'n\gamma X$. The line defines the cut on P_X . The data (black circles) are compared with simulations of neutron DVCS (red triangles) and of partially reconstructed π^0 background (blue upside-down triangles). The simulations are rescaled to match, approximately, the relative weights of each contribution to the data. The green squares are the sums of the two simulated contributions.

FIG. 3. Q^2 versus x_B for the nDVCS data sample with all selection cuts applied, showing the wide kinematic reach of CLAS12.

selection criteria for the DVCS process to fully reconstructed $e'n\pi^0$ events was computed. Multiplying this ratio by the number of reconstructed $e'n\pi^0$ events in the data yields the number of $e'n\pi^0(1\gamma)$ events. This number was then subtracted from the yield of DVCS event candidates in each kinematic bin and helicity state. The π^0 contamination ranges from 10% to 45% depending on the kinematics.

The BSA is obtained for each kinematic bin as

$$A_{LU} = \frac{1}{P} \frac{N^+ - N^-}{N^+ + N^-}, \quad (5)$$

where P is the average beam polarization and $N^{+(-)}$ is the yield of DVCS events for positive (negative) beam helicity after π^0 subtraction. Radiative corrections were estimated according to Ref. [51] and found to be negligible.

Various sources of systematic uncertainty on the BSA were studied. To obtain the systematic uncertainty due to the cut on the boosted decision tree classifier to remove the proton contamination and on the exclusivity cuts, variations around each chosen cut were made, and the differences between the resulting BSAs were taken as the systematic uncertainty. The systematic uncertainty on the beam polarization was the standard deviation of the polarization measured by the Møller polarimeter. The systematic uncertainty stemming from the merging of datasets with different beam energy was evaluated with a GPD-based model computing the BSA stemming from the interference of DVCS and BH. The systematic uncertainty induced by the π^0 subtraction method was estimated using a different method, relying on the statistical unfolding [52] of signal and background contributions to the $MM_{e'n\gamma X}^2$ spectrum (Fig. 2, left), and comparing the obtained BSAs in each kinematic bin. The total systematic uncertainty was computed by summing all contributions in quadrature. It is, on average, ~ 0.01 , and largely dominated by the uncertainty on the exclusivity cuts.

FIG. 4. Beam-spin asymmetry for nDVCS versus ϕ for (top) three bins in $-t$ ($[0, 0.3]$, $[0.3, 0.5]$, and $[0.5, 1.1]$ GeV^2), (middle) three bins in x_B ($[0.05, 0.14]$, $[0.14, 0.2]$, and $[0.2, 0.6]$), and (bottom) three bins in Q^2 ($[1, 1.9]$, $[1.9, 2.9]$, and $[2.9, 6]$ GeV^2). The error bars are statistical. The data are fit with the function $A_{LU}(90^\circ) \sin \phi$. The boxes represent the total systematic uncertainty.

The BSA, which was extracted in bins of either Q^2 , x_B , or t , is plotted as a function of ϕ in Fig. 4. It has the expected sinusoidal shape arising from the DVCS-BH interference, and is fitted by the function $A_{LU}(90^\circ) \sin \phi$. Its amplitude is on the order of a few percent, about a factor of 4 smaller than the pDVCS amplitude measured at these same kinematics [20]. The systematic uncertainty is smaller than the statistical one in most cases.

Figure 5 shows the amplitude $A_{LU}(90^\circ)$ of the $\sin \phi$ fits to the BSA as a function of Q^2 (left), x_B (middle), and $-t$ (right). The data are compared to predictions for DVCS on a free neutron of the Vanderhaeghen-Guichon-Guidal model [53] for different values of the quark total angular momenta J_u and J_d . The VGG model uses double distributions [1,4] to parametrize the (x, ξ) dependence of the GPDs, and Regge phenomenology for their t dependence. The model curves are obtained at the average kinematics for Q^2 , x_B , and $-t$, and setting ϕ at 90° . The values of J_u and J_d were varied in a grid of step 0.025 and range ± 1 , and the χ^2 of each obtained model curve with the data points was computed. Three of the curves yielding the best χ^2 are retained for Fig. 5. Considering χ^2 values within 3σ from the minimum, in the VGG framework the data favor d quark angular momenta $0 < J_d < 0.2$, while no constraints can be imposed on J_u . The model does not reproduce the kinematic dependence of $A_{LU}(90^\circ)$, predicting steeper variations, in particular for $-t$, than those displayed by the data.

The sensitivity of the CLAS12 nDVCS BSA to CFFs, in particular to $\Im m \mathcal{E}$, was tested by including it in a fit of

FIG. 5. The $\sin\phi$ amplitude of A_{LU} for nDVCS as a function of Q^2 (left), x_B (middle), and $-t$ (right). The (red online) bands represent the systematic uncertainties. The VGG model [53] predictions for three of the combinations of J_u and J_d yielding the best χ^2 are compared to the data: solid black line for $J_u = 0.35$ $J_d = 0.05$, dashed-dotted red line for $J_u = -0.2$ $J_d = 0.15$, and blue dotted line for $J_u = -0.45$ $J_d = 0.2$.

CFFs by the output of neural networks as an effective parametrization, serving as unbiased interpolation function [54]. Here, values at network inputs represent the kinematical variables x_B , Q^2 , and t , and values at outputs represent the imaginary and real parts of the up and down quark contributions to CFFs. The networks were trained on 200 Monte Carlo replicas of the experimental data, which ensured that uncertainty of the resulting CFFs is faithfully propagated from the experimental measurements. Figure 6 shows the up and down quark $\Im m\mathcal{H}$ and $\Im m\mathcal{E}$ CFFs, extracted by fits to old CLAS [16,17] and HERMES [25,27] proton data, to recent CLAS12 proton

FIG. 6. Extraction of up (u , coarser red shading) and down (d , finer blue shading) quark contributions to $\Im m\mathcal{H}$ (top) and $\Im m\mathcal{E}$ (bottom) as a function of $-t$ (left and middle) and ξ (right). The leftmost column shows the extraction of the two CFFs without the CLAS12 nDVCS data, which are instead included in the other two columns.

data [20] and to the neutron data reported here. Note that the Hall A nDVCS data were not included in this study in order to assess the impact of the present data alone. While the inclusion of the CLAS12 nDVCS data allows the flavor separation of $\Im m\mathcal{H}$, the main new result is the flavor separation of $\Im m\mathcal{E}$. The same CFF extraction method was previously used to attempt flavor separation of the CFFs of H and E [55] by combining pDVCS data and the Hall A nDVCS results [36]. While promising results were obtained for $\Re e\mathcal{H}$ and $\Im m\mathcal{H}$, the separation was not possible for the CFFs of E . The small systematic uncertainties of the CLAS12 nDVCS data, obtained mainly thanks to the detection of the neutron, and their wide kinematic coverage provide the necessary sensitivity for the flavor separation of $\Im m\mathcal{E}$.

The CLAS12 nDVCS data represent an important step toward the understanding of the contribution of the angular momentum of the quarks to the spin of the nucleon via Ji's sum rule, of which the GPD E is an essential, yet poorly known, ingredient. The future increase in statistics of the nDVCS dataset, which will be achieved both by upgrades of the CLAS12 reconstruction software and by additional data, will allow better precision and four-dimensional binning for the BSA, and thus a more accurate mapping of $\Im m\mathcal{E}$. An ongoing analysis of this same dataset aims to extract cross sections for nDVCS, which are sensitive to $\Re e\mathcal{E}$. Furthermore, CLAS12 recently completed an experiment with a longitudinally polarized deuterium target, which will yield target-spin asymmetries and double-spin asymmetries for nDVCS. These observables, combined with the unpolarized-target ones, will contribute to constrain more CFFs of the neutron, hence to progress in the flavor separation of all four GPDs, and, consequently, to deepen our understanding of the properties of the nucleons in terms of their elementary constituents.

Acknowledgments—We thank very much the staff of the Accelerator and the Physics Divisions at Jefferson Lab for making the experiment possible. This work was supported in part by the U.S. Department of Energy (DOE) and National Science Foundation (NSF), the Italian Istituto Nazionale di Fisica Nucleare (INFN), the French Centre National de la Recherche Scientifique (CNRS), the French Commissariat à l'Énergie Atomique (CEA), the Scottish Universities Physics Alliance (SUPA), the National Research Foundation of Korea (NRF), the UK Science and Technology Facilities Council (STFC), the Chilean Agencia Nacional de Investigación y Desarrollo (ANID), and the Croatian Science Foundation. This work was supported as well by the EU Horizon 2020 Research and Innovation Program under the STRONG-2020 Grant Agreement No. 824093 and the Marie Skłodowska-Curie Grant Agreement No. 101003460. The Southeastern

Universities Research Association (SURA) operates the Thomas Jefferson National Accelerator Facility for the U.S. Department of Energy under Contract No. DE-AC05-06OR23177.
