Abstract. The North Atlantic Climate System Integrated Study (ACSIS) was a large multidisciplinary research programme funded by the UK's Natural Environment Research Council (NERC). ACSIS ran from 2016 to 2022

and brought together around 80 scientists from seven leading UK-based environmental research institutes to deliver major advances in the understanding of North Atlantic climate variability and extremes. Here, we present an overview of the data generated by the ACSIS programme. The datasets described cover the North Atlantic Ocean, the atmosphere above it (including its composition), and Arctic sea ice.

Atmospheric composition datasets include measurements from seven aircraft campaigns (45 flights in total, 0–10 km altitude range) in the northeastern Atlantic ($\sim 15\text{--}55^\circ\text{N}$, $\sim 40^\circ\text{W}\text{--}5^\circ\text{E}$) made at intervals of 6 months to 2 years between February 2017 and May 2022. The flights measured chemical species (including greenhouse gases; ozone precursors; and volatile organic compounds – VOCs) and aerosols (organic aerosol – OA; SO_4 ; NH_4 ; NO_3 ; and non-sea salt chloride – nss-Cl) (<https://doi.org/10.5285/6285564c34a246fc9ba5ce053d85e5e7>, FAAM et al., 2024). Ground-based stations at the Cape Verde Atmospheric Observatory (CVAO), Penlee Point Atmospheric Observatory (PPAO), and Plymouth Marine Laboratory (PML) recorded ozone, ozone precursors, halocarbons, greenhouse gases (CO_2 and methane), SO_2 , and photolysis rates (CVAO; <http://catalogue.ceda.ac.uk/uuid/81693aad69409100b1b9a247b9ae75d5>, National Centre for Atmospheric Science et al., 2010); O_3 and CH_4 (PPAO, <https://catalogue.ceda.ac.uk/uuid/8f1ff8ea77534e08b03983685990a9b0> (Plymouth Marine Laboratory and Yang, 2017); and aerosols (PML, <https://doi.org/10.5285/e74491c96ef24df29a9342a3d57b5939>, Smyth, 2024), respectively.

Complementary model simulations of atmospheric composition were performed with the UK Earth System Model (UKESM1) for the period from 1982 to 2020 using Coupled Model Intercomparison Project Phase 6 (CMIP6) historical forcing up to 2014 and Shared Socioeconomic Pathways (SSP) scenario SSP3-7.0 from 2015 to 2020. Model temperature and winds were relaxed towards ERA reanalysis. Monthly mean model data for ozone, NO, NO_2 , CO, methane, stratospheric ozone tracers, and 30 regionally emitted tracers are available for download (<https://data.ceda.ac.uk/badc/acsis/UKESM1-hindcasts>, Abraham, 2024).

AC SIS also generated new ocean heat content diagnostics (<https://doi.org/10/g6wm>, <https://doi.org/10/g8g2>, Moat et al., 2021a–b) and gridded temperature and salinity based on objectively mapped Argo measurements (<https://doi.org/10.5285/fe8e524d-7f04-41f3-e053-6c86abc04d51> King, 2023).

An ensemble of atmosphere-forced global-ocean sea-ice simulations using the NEMO-CICE model was performed with horizontal resolutions of $1/4$ and $1/12^\circ$ covering the period from 1958 to 2020 using several different atmosphere-reanalysis-based surface forcing datasets, supplemented by additional global simulations and stand-alone sea-ice model simulations with advanced sea-ice physics using the CICE model (<http://catalogue.ceda.ac.uk/uuid/770a885a8bc34d51ad71e87ef346d6a8>, Megann et al., 2021e). Output is stored as monthly averages and includes 3D potential temperature, salinity, zonal velocity, meridional velocity, and vertical velocity; 2D sea-surface height, mixed-layer depth, surface heat, and freshwater fluxes; ice concentration and thickness; and a wide variety of other variables.

In addition to the data presented here, we provide a very brief overview of several other datasets that were generated during ACSIS and have been described previously in the literature.

1 The North Atlantic climate system

The North Atlantic Climate System Integrated Study (AC SIS) was a 6-year research programme (2016–2022) commissioned by the UK Natural Environment Research Council (NERC) as part of the first wave of a new series of Long-Term Science Multi-centre (LTSM) programmes. AC SIS connected research in the physical and chemical components of the atmosphere–hydrosphere–cryosphere nexus within the North Atlantic region and provided an opportunity for NERC scientists from different disciplines to come together and deliver new insights into a region undergoing rapid change in the ocean and atmosphere temperatures and circulation; sea-ice thickness and extent; and key atmospheric constituents, such as ozone, methane, and aerosols (Sutton et al., 2018). The ACSIS team included members of

the National Centre for Atmospheric Science (NCAS), Plymouth Marine Laboratory (PML), the National Oceanography Centre (NOC), the British Antarctic Survey (BAS), the National Centre for Earth Observation (NCEO), the Centre for Polar Observation and Modelling (CPOM), and the Met Office.

AC SIS was designed to answer the following key questions about the North Atlantic climate system:

1. How have changes in natural and anthropogenic emissions and atmospheric circulation combined to shape multiyear trends in the North Atlantic atmospheric composition and radiative forcing?
2. How have natural variability and radiative forcing combined to shape multiyear trends in the North Atlantic physical climate system?

3. To what extent are changes in the North Atlantic climate system predictable on multiyear timescales?

In order to answer these questions, ACSIS was arranged into a series of interlinked work packages involving a broad representation of scientists from the different NERC centres involved in ACSIS. These work packages delivered new scientific understanding, delivered through several key synthesis papers (Sutton et al., 2018; Robson et al., 2018, 2020; Hirschi et al., 2020) as well as a wealth of data. The objectives of ACSIS were as follows:

- a. to provide the UK science community with sustained observations, data syntheses, leading-edge numerical simulations and analysis tools to facilitate world-class research on changes in the North Atlantic climate system and their impacts;
- b. to provide a quantitative and multivariate description of how the North Atlantic climate system is changing;
- c. to determine the primary drivers and processes that are shaping changes in the North Atlantic climate system now and will shape changes in the near future;
- d. to determine the extent to which future changes in the North Atlantic climate system are predictable.

In this paper we focus on objective (a) of the ACSIS project, which included the creation of new datasets to underpin the ACSIS project and support wider work on the North Atlantic climate system by the UK and international science communities.

In this paper we outline the underpinning datasets generated as part of the ACSIS project, how they can be obtained (guided by the FAIR principles; Wilkinson et al., 2016), and the motivation for their creation.

1.1 Overview of data holdings

A summary of the datasets that are generated by ACSIS and freely available to the community is given in Table 1. Note that the new data presented in this paper are archived across two platforms: the British Oceanographic Data Centre (<https://www.bodc.ac.uk>, last access: 19 December 2024; ocean observations) and the Centre for Environmental Data Analysis (<https://www.ceda.ac.uk>, last access: 19 December 2024; all other data). A schematic map giving an overview of the footprints of all of the observational datasets can be found in Fig. 1. The three general areas covered are as follows: atmospheric composition, covering aircraft and ground station data along with nudged historical atmospheric chemistry/circulation model simulations; ocean observations, covering gridded in situ temperature and salinity (0–2000 m) and 0–1000 m heat content; forced historical ocean-ice simulations at eddy-permitting and eddy-resolving resolutions and stand-alone Arctic sea-ice simulations. In Sects. 2, 3, and 4,

we describe the individual archived datasets in detail. Several other datasets, previously described in the literature, have been generated by the ACSIS programme including simulations to generate volcanic forcing data for climate models, coupled climate model simulations with a high-resolution atmosphere and/or ocean, gridded sea-surface temperature based on in situ ocean observations, and observation-based estimates of the Atlantic Meridional Overturning Circulation (AMOC) and Arctic-wide sea-ice thickness. We anticipate that all of the different types of data used here could be used in synergy, and users should consider the different uncertainties associated with the different datasets. In particular, modelled ice, ocean, and atmospheric composition are forced by a variety of different atmospheric meteorological data, and this may introduce some further uncertainty into the attribution of trends and variability across the different realms. For completeness (and because the new datasets described here will likely be used in conjunction with existing published datasets), we provide a very brief overview of the latter in Sect. 5.

2 Composition datasets

The composition of the atmosphere is changing at an unprecedented pace. Changes in the levels of stratospheric ozone, surface ozone, and other secondary pollutants are driven by human activities (e.g. Griffiths et al., 2021; Keeble et al., 2021; Turnock et al., 2020). The North Atlantic region has undergone significant growth and decline in air pollution over the last 3 decades, and modelling studies have all shown the significant human health benefits of these more recent reductions (Turnock et al., 2016; Archibald et al., 2017; Daskalakis et al., 2016). However, whilst we have a broad understanding of the distribution of key air pollutants and short-lived climate forcers, our understanding of the variability in these species and their trends is hampered across the North Atlantic owing to a paucity of observations. The North Atlantic is frequently impacted by the transport of transboundary pollution from anthropogenic sources and fires (Boylan et al., 2015; Helmig et al., 2015; Kumar et al., 2013) as well as from local natural marine and shipping emissions (e.g. Yang et al., 2016a). High-altitude research stations in the eastern North Atlantic in the Azores (Mount Pico) and Canary Islands (Izaña) and coastal observatories on the west coast of Ireland (Mace Head), and in the Republic of Cabo Verde have provided long-term datasets with which to better understand the sources and processes controlling reactive trace gases and aerosols across the North Atlantic.

In ACSIS, a series of work packages were conducted to (a) further our understanding of the distribution and variability of key trace gases and aerosols using aircraft campaigns and long-term measurements, (b) understand the processes controlling these, and (c) improve model simulations, which can be used to forecast the future evolution of these species.

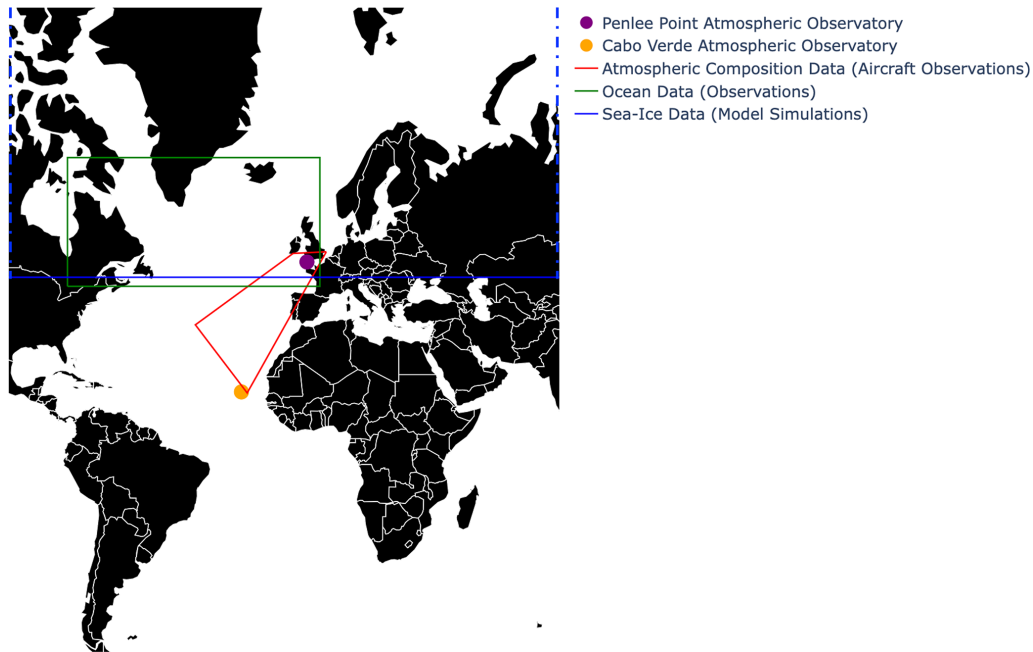

Figure 1. Schematic overview of the footprints of all of the observational datasets presented in this paper.

In the following sections, we outline the data that were generated to support these objectives.

2.1 Aircraft campaigns in the North Atlantic

During ACSIS, approximately biannual gas and aerosol composition measurements were made during aircraft missions from the UK to the Azores, focusing on obtaining vertical context for composition, to complement surface observations and provide linkage with satellite data.

Measurements were collected using the UK's Atmospheric Research Aircraft (ARA). The ARA is a BAe 146-301 which has been in service since 2004 and is managed by the Facility for Airborne Atmospheric Measurements (FAAM), an airborne laboratory funded by the UK government. The FAAM aircraft is capable of carrying a 4 t instrument load and can operate at altitudes between 50 and 30 000 ft (15–9140 m), allowing the study of processes in the troposphere and boundary layer. ARA missions as part of ACSIS provide the longest record of composition change in the lower free troposphere over the North Atlantic (Sutton et al., 2018) and further complement historic research flights conducted with the ARA in the region (e.g. Parrington et al., 2012; Reeves et al., 2002) as well as more recent flights by other platforms (e.g. ATom – Wofsy et al., 2018; NAAMES – e.g. Behrenfeld et al., 2019, and Sinclair et al., 2020; and ACE-ENA – Zawadowicz et al., 2021).

2.1.1 Campaign flights

A series of (daytime) research flights were carried out across the North Atlantic Ocean from February 2017 to May 2022. Figure 2 shows the location of the ACSIS flight tracks, colour-coded by the campaign number. There were a total of 45 flights as part of the ACSIS campaign, comprising close to 200 h of measurement data. Measurements were made from approximately 50 m over the sea surface to 9140 m. ACSIS 1, 2, 4, 5, and 7 were predominantly based out of the Azores, whilst flights for ACSIS 3 were based out of Cork, Ireland, and ACSIS 6 flights were based out of Cabo Verde.

Also shown in Fig. 2 are parts of the flight tracks for the NASA Atmospheric Tomography Mission (ATom) mission. The ATom campaigns aimed to improve the representation of reactive gases and short-lived climate forcers in global atmospheric chemistry and climate models by measuring atmospheric composition along a global circuit flight track (Prather et al., 2017). Four ATom campaigns occurred between August 2016 and May 2018. The ATom dataset is complementary to that collected during the ACSIS flight campaigns; ATom flights provided a broad overview at a global scale, whereas ACSIS flights intensively measured the North Atlantic region. ACSIS 1 overlapped with ATom 2 and ACSIS 2 overlapped with ATom 3.

2.1.2 Instrumentation

A wide range of instrumentation is fitted on the ARA, including measurements of key meteorological parameters (such as temperature, humidity, wind speed, and direction)

Table 1. Overview of the data described in this paper with links to the subsections in which the data are described in detail.

Title	Data, URL, and citation	Accessibility	Section(s)
Aircraft missions	Gas and aerosol data were collected aboard the Facility for Airborne Atmospheric Measurements (https://catalogue.ceda.ac.uk/uuid/6285564c34a246fc9ba5ce053d85e5e7/ , FAAM et al., 2024).	Data are open access for the merged 10s product, but registration/login to CEDA is required for full temporal resolution.	2.1
Ground-based observational atmospheric composition time series	Atmospheric composition, including ozone, methane, carbon monoxide, volatile organic compounds (VOCs), and aerosol parameters were from the Cape Verde Atmospheric Observatory (CVAO; http://catalogue.ceda.ac.uk/uuid/81693aad69409100b1b9a247b9ae75d5 , National Centre for Atmospheric Science et al., 2010), Penlee Point Atmospheric Observatory (PPAO; https://catalogue.ceda.ac.uk/uuid/8f1ff8ea77534e08b03983685990a9b0 , Plymouth Marine Laboratory and Yang, 2017), and Plymouth Marine Laboratory (https://catalogue.ceda.ac.uk/uuid/e74491c96ef24df29a9342a3d57b5939 , Smyth, 2024).	CVAO data require registration/login to CEDA; PPAO and PML data are open access.	2.2, 2.3
Nudged atmospheric model simulations with atmospheric composition	Data comprise the simulated atmospheric composition from 1981 to 2020 with atmospheric circulation nudged to ERA5 reanalysis (https://data.ceda.ac.uk/badc/acsis/UKESM1-hindcasts , Abraham, 2024).	Data are open access for selected atmospheric composition variables, but registration/login via a JASMIN Met Office MASS account is required for access to the comprehensive dataset.	2.4
Ocean circulation and heat content	Data comprise objectively interpolated (gridded) ocean temperature and salinity (0–2000 m; https://doi.org/10.5285/fe8e524d-7f04-41f3-e053-6c86abc04d51 ; King, 2023) and upper-ocean (0–1000 m) heat content time series (https://doi.org/10/g6wm , Moat et al., 2021a; https://doi.org/10/g8g2 , Moat et al., 2021b).	Data are open access.	3.1
Ocean sea-ice and stand-alone sea-ice simulations	Data comprise NEMO-CICE global-ocean simulations with default sea-ice physics at 1, 1/4, and 1/12° up to 2020 (https://doi.org/10.5285/119a5d4795c94d2e94f610647640edc0 , Megann et al., 2021b; https://doi.org/10.5285/a0708d25b4fc44c5ab1b06e12fef2f2e , Megann et al., 2021c; https://doi.org/10.5285/4c545155dfd145a1b02a5d0e577ae37d , Megann et al., 2021d; https://doi.org/10.5285/e02c8424657846468c1ff3a5acd0b1ab , Megann et al., 2022a; https://doi.org/10.5285/399b0f762a004657a411a9ea7203493a , Megann et al., 2022b) as well as NEMO-CICE global-ocean simulations with improved sea-ice physics at 1/4° up to 2020 and stand-alone Arctic sea-ice simulations (http://catalogue.ceda.ac.uk/uuid/770a885a8bc34d51ad71e87ef346d6a8 , Megann et al., 2021e).	Data are open access.	3.2.2, 4.1

and a range of in situ trace gas measurements (including carbon monoxide, CO; ozone, O₃; oxides of nitrogen, NO_x = NO + NO₂; and the greenhouse gases carbon dioxide, CO₂, and methane, CH₄). Table 2 summarizes the measurement techniques, uncertainties, and limit of detection (i.e. precision 3σ) aboard the ARA that were used during ACSIS flights.

2.1.3 Vertical distribution of pollutants

Data collected during flights from all seven ACSIS campaigns have been analysed together to give insights into the spatial and vertical characteristics of atmospheric composition over the North Atlantic Ocean. Data from all seven campaigns have been combined and grouped into 1000 m altitude bins. Figure 3 shows the vertical distribution of O₃, CO, CO₂, CH₄, NO, and NO₂.

Table 3 summarizes the flights and times that were used in this bulk analysis.

2.1.4 Data archive

To accompany this paper, a 10 s averaged merged file has been created for each flight listed in Table 3 (<https://catalogue.ceda.ac.uk/uuid/6285564c34a246fc9ba5ce053d85e5e7/>, Facility for Airborne Atmospheric Measurements et al., 2024). The merged files are open access and designed to be a tool for an initial exploration of the data and to highlight the breadth of the atmospheric composition data collected during the ACSIS programme. However, for further analysis, the original-frequency data should be used; details on where these files can be found is included in the header information of the merged files. The merged files are in ASCII format and consist of a short explanatory paragraph followed by a list of

variables and finally the data arranged as columns, with one variable per column, with rows corresponding to the values at each 10 s time interval.

2.2 Cape Verde Atmospheric Observatory (CVAO)

ACSIS supported composition measurements at Cabo Verde from 2016 to 2021 in order to deliver quantitative analyses of composition variability and its relationship to other climate parameters; trend analyses on the long-term surface-based datasets; and understanding of how these link to patterns identified in the aircraft and satellite observations.

The Global Atmospheric Watch (GAW) Cape Verde Atmospheric Observatory (<https://amof.ac.uk/observatory/cape-verde-atmospheric-observatory-cvao/>, last access: 19 December 2024) is situated in Calhau on the island of São Vicente in the Republic of Cabo Verde (16.848°N, 24.871°W; 10 m above sea level). Measurements were started in October 2006 to further our understanding of atmospheric chemistry within the tropical marine boundary layer and North Atlantic region. The site receives air from a wide variety of sources with 10 d back trajectories reaching to North America, Europe, and sub-Saharan Africa (see Carpenter et al., 2010, for details). Long-term high-frequency measurements allow investigation into the trends of climate gases such as CO₂ and CH₄, whilst measurements of pollutants from the continents (such as hydrocarbons and nitrogen oxides) provide better constraints of global emission changes and their effect on the long-term background of the North Atlantic (e.g. Helmig et al., 2016). The observatory regularly hosts field campaigns that focus on process studies such as sea-surface interactions and the role of aerosols in atmospheric chemistry (Read et al., 2008; McFiggans et al., 2009; Lawler et al., 2011; van Pinxteren et al., 2020).

2.2.1 Time series of meteorological parameters and chemical composition

Table 4 provides a summary of the chemical species recorded at the CVAO, and Fig. 4 shows time series of meteorological parameters and concentrations of chemical species. During ACSIS, these time series were used to estimate trends, particularly in ozone, carbon monoxide, methane, and NO_x. Here, we make some general observations concerning the time series of these four species. Ozone concentrations at the CVAO show seasonal variability, with the highest concentrations in spring and the lowest in summer, consistent with ozone's role as a secondary pollutant. In summer, the site occasionally receives air from the Southern Hemisphere during the early stages of the Atlantic cyclonic activity, which leads to

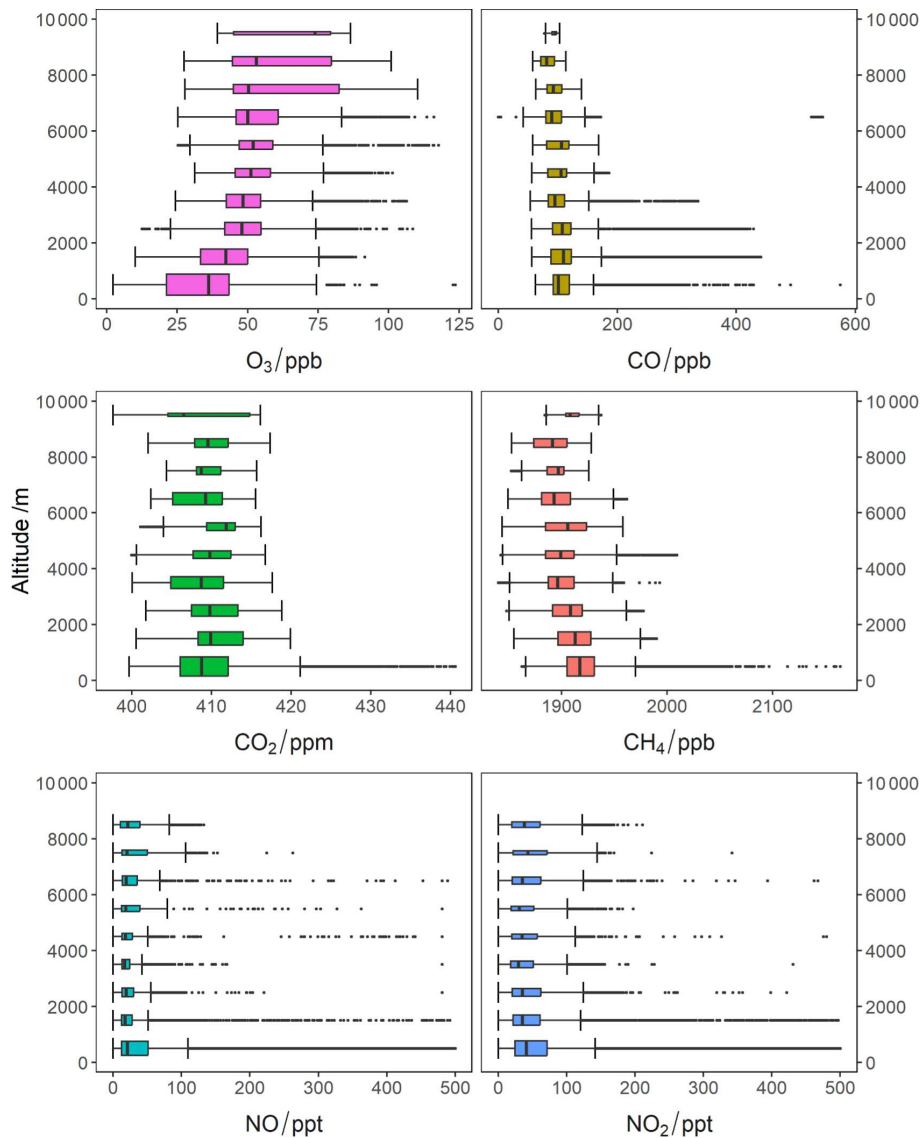

Figure 3. Box plots showing the vertical distribution of O₃, CO, CO₂, CH₄, NO, and NO₂ for all seven ACSIS campaigns. The vertical line in the centre of each box represents the median value, while the edges of the boxes show the 25th and 75th percentiles. The bars extending from the box show the minimum and maximum values no more than 1.5 times the interquartile range. The height of the box is proportional to the number of observations within each altitude bin, with taller boxes corresponding to a higher number of observations. Note that sporadic high mixing ratios of CO, NO, and NO₂ at low altitudes, likely due to local pollution sources, have been filtered so that the bulk of the data is clearly shown. Cutoff values of 600 ppbv for CO and 500 pptv for NO and NO₂ were used. The NO_x instrument has a ceiling of ~8200 m, so there are no data for the 9000–10 000 m bin.

very low concentrations of ozone (< 10 ppb) observed along with episodes of intense precipitation. Carbon monoxide is a primary pollutant emitted from anthropogenic sources and from biomass burning. Since 2008, CO has been decreasing at CVAO. Global methane concentrations have increased substantially over the last 10 years, attributed to increased primary emissions of hydrocarbons and increased emissions from wetlands due to increasing temperatures (Jackson et al., 2020; Thompson et al., 2018). At CVAO, methane has been increasing steadily. Concerning NO_x, in extremely clean air

containing low levels of CO and volatile organic compounds (VOCs), Andersen et al. (2022) showed good agreement between NO₂ levels observed at the CVAO and those derived from the photostationary state (PSS), utilizing measured NO, O₃, and jNO₂ and photochemical box model predictions of peroxy radicals. However, in clean air containing small amounts of aged pollution, as typically encountered in winter, higher levels of NO₂ were observed than inferred from the PSS, implying underestimation of peroxy radicals or unattributed NO₂ measurement artefacts.

Table 4. Summary of atmospheric data recorded at CVAO.

Measurement ^a	Instrumentation ^b	Time resolution	Precision (1 h)	Timescale
O ₃	Thermo Scientific Model 49i ozone monitor	10 s	0.5 ppb	2006–present
CO	Aero-Laser AL5001/Picarro G4201	4 s	1 ppb	2008–present
NO	Chemiluminescence instrument, Air Quality Design Inc.	5 min	1.4 ppt	2006–present
NO ₂	Chemiluminescence instrument, Air Quality Design Inc.	5 min	4.4 ppt	2017–present
VOCs	GC-FID	1 h		2006–present
OVOCs	GC-FID	1 h		2014–present
Short-lived halocarbons	GC-TOF-MS	1 h		2014–present
CFCs/HCFCs	GC-TOF-MS	1 h		2022–present
DMS	GC-FID	1 h		2012–present
Photolysis rates	Spectral radiometer	1 min		2016–present
CO ₂	Picarro G4201	4 s	10 ppb	2012–present
CH ₄	Picarro G4201	4 s	0.3 ppb	2012–present
SO ₂	Thermo Scientific Model 43i HL	5 s		2019–present
Total gaseous mercury	Tekran	1 min		2014–2019

^a VOCs – volatile organic compounds; OVOCs – oxygenated volatile organic compounds; CFCs/HCFCs – chlorofluorocarbons/hydrochlorofluorocarbons; DMS – dimethyl sulfide.

^b GC-FID – gas chromatography flame ionization detector; GC-TOF-MS – gas chromatography time-of-flight mass spectroscopy.

2.2.2 Data archive

Cabo Verde data collected under the auspices of ACSIS are available from CEDA: <http://catalogue.ceda.ac.uk/uuid/81693aad69409100b1b9a247b9ae75d5> (National Centre for Atmospheric Science et al., 2010). Note that there are a number of subdirectories, some of which are not relevant to the data described in this paper. The relevant subdirectories are labelled with the variable or variable group and the time period, e.g. “Cape Verde Atmospheric Observatory: Ozone measurements (2006 onwards)”. The data format is ASCII, consisting of a header explaining the variables listed followed by the data in columnar format (one column per variable), with the data values in rows appearing in chronological order. We note that specific Cabo Verde data are also archived at the World Data Centre for Greenhouse Gases (<https://gaw.kishou.go.jp>, last access: 19 December 2024; CO₂, CH₄, and CO) and at EBAS (<https://ebas.nilu.no>, last access: 19 December 2024; VOCs, NO_x, SO₂, and halocarbons).

2.3 Penlee Point Atmospheric Observatory

As with CVAO, ACSIS also supported atmospheric composition observations at Penlee Point, UK. Situated on the eastern edge of the North Atlantic, the Penlee Point Atmospheric Observatory (PPAO; 50°19.08' N, 4°11.35' W; <https://www.westernchannelobservatory.org.uk/penlee/>, last access: 19 December 2024) was established by the Plymouth Marine Laboratory (PML) in 2014 on the southwestern coast of the UK. PPAO is a few tens of metres from the water edge and about 11 m above mean sea level. The site is exposed to marine air over a very wide sector (wind directions of ~ 110–260°). Typical southwesterly winds tend to bring relatively clean background air from the North Atlantic, with little terrestrial influence. Winds from the south-

east are often contaminated by exhaust plumes from passing ships, while winds from the north are influenced by terrestrial emissions. We are particularly interested in the North Atlantic air mass at this coastal location, as this represents the background condition for the UK during the typical southwesterly conditions.

In close proximity to the Western Channel Observatory marine sampling stations, high-frequency observations at PPAO enable both long-term monitoring of trends and process-based studies of atmosphere–ocean interactions. Current/recent work has assessed trace gas burdens and air–sea fluxes, including greenhouse gases (Yang et al., 2016b, c, 2019a); volatile organic carbon (Phillips et al., 2021); and sulfur- (Yang et al., 2016c), halogen- (Sommariva et al., 2018), and nitrogen-containing gases (ongoing). Further works include aerosol composition and fluxes, with particular foci on ship emissions (ongoing as a part of the ACUISE project), sea-spray production (Yang et al., 2019b), macro/micronutrient deposition (White et al., 2021), and reaction between atmospheric ozone and the sea-surface microlayer (Loades et al., 2020).

Continuous observations most relevant to ACSIS include ground-based ozone and methane from PPAO as well as column aerosols from the rooftop of PML (10 km north/northeast of PPAO). These measurements are detailed in Table 5.

2.3.1 Ozone

Due to the short lifetime of O₃, it is sensitive to local sources/sinks and heterogeneities associated with a coastal environment. This presents a good opportunity to compare two different methods of identifying the southwest (i.e. Atlantic) wind sector: (1) by air mass dispersion history (NAME – Numerical Atmospheric-dispersion Modelling Environment; see e.g. Yang and Fleming, 2019) and (2) by local wind direction. Data from the first 2 years of observations

Figure 4. Time series of weekly averaged Cabo Verde data showing a range of species and meteorological parameters measured from 7.5 m between 2016 and 2023. From the top, the parameters are as follows: wind speed (*ws*), temperature (*T*), ozone (O_3), methane (CH_4), ethane (C_2H_6), nitrogen monoxide (NO), nitrogen dioxide (NO_2), carbon monoxide (CO), sulfur dioxide (SO_2), carbon dioxide (CO_2), ethene (C_2H_2), methyl iodide (CH_3I), bromoform ($CHBr_3$), and chloroform ($CHCl_3$).

Table 5. Overview of the measurements made at PPAO.

Measurement	Instrumentation	Time resolution	Accuracy	Timescale
O_3	(a) 2B Technologies Model 205 ozone monitor (b) Thermo Scientific Model 49i ozone monitor	10 s	≤ 1 ppb	(a) May 2014–Sep 2018 (b) Sep 2018–present
CH_4	(a) Picarro G2311-f (b) Los Gatos Research FGGA	0.1 s until Aug 2016; 1 s since Aug 2016	≤ 3 ppb	(a) May 2014–Sep 2015 (b) Sep 2015–present
Aerosols	POM sun photometer	10 min (under clear-sky and daytime conditions)	≤ 0.01 at 550 nm	2001–present

(May 2014 to April 2016, when NAME model output was available) show that defining the PPAO open-ocean sector either by local wind direction (210 to 260°) or by air mass history (> 80 % in the Atlantic Ocean region over the last 5 d) yields fairly comparable results, with a mean difference of about 1.5 ppb. We conclude that the North Atlantic air mass can reasonably be identified from the local wind direction between 210 and 260°, and we use this definition in Sect. 2.3.2 below.

2.3.2 Methane

As shown in Fig. 5, the overall mean CH₄ mixing ratio is about 0.02–0.03 ppm higher than the mean CH₄ from the southwest wind sector (defined as wind direction between 210 and 260° here). This illustrates the importance of considering wind sectors in the interpretation of coastal observations. The long-term trends in the CH₄ mixing ratio are similar with or without the wind sector consideration and are in line with observations made globally (e.g. Nisbet et al., 2019). We expect measurements from the southwest wind sector to be more representative of the Atlantic and, thus, background Northern Hemisphere. That the all-direction mean mixing ratio is higher reflects local and regional emissions of methane.

Methane shows a mean seasonal amplitude of ~0.03 ppm (relative difference of ~1.5 %). The summer minimum is most likely due to an increased sink of methane by the OH radical. These data suggest no significant deviation from the long-term trend over the last few years (2019–2022), when it has been postulated that the COVID lockdowns changed the atmospheric oxidizing capacity and, thus, the OH sink (e.g. Monks et al., 2015).

2.3.3 Aerosols from sun photometers

Long-term aerosol measurements (starting from 2001) have been made from the rooftop of PML (50.3661° N, 4.1482° W; about 10 km north-northeast of Penlee Point). The retrieved, cloud-filtered data are averaged to monthly intervals (as shown in Fig. 6a). Overall, there is no obvious long-term trend in the aerosol optical depth (AOD) at this site, in contrast to many other locations in western Europe that tend to show a gradual reduction. This may be because of the predominance of sea-spray aerosols at this location (Yang et al., 2019b).

The inferred size distributions are also shown (Fig. 6b). The volume distribution ($dV/d\log(R)$) is dominated by supermicron aerosols, while the number distribution ($dN/d\log(R)$) is dominated by submicron aerosols. There appears to be a gradual reduction in the springtime aerosol maximum at around 100 nm radius from 2010 to 2021, which could be related to reduced terrestrial or ship anthropogenic emissions (e.g. due to air-quality-related regulations).

2.3.4 Data archive

Penlee Point Atmospheric Observatory data are archived at CEDA: <https://catalogue.ceda.ac.uk/uuid/8f1ff8ea77534e08b03983685990a9b0> (Plymouth Marine Laboratory and Yang, 17). Data from the PML sun photometer can be found at <https://doi.org/10.5285/e74491c96ef24df29a9342a3d57b5939> (Smyth, 2024). The data format is ASCII, consisting of a header explaining the variables listed followed by the data in columnar format (one column per variable), with the data values in rows appearing in chronological order.

2.4 Atmospheric composition modelling with UK Earth System Model (UKESM1)

To complement the observational data, ACSIS performed climate model experiments with full atmospheric chemistry included. The experimental design for these simulations was focussed around providing simulations and output that could support observational campaigns and allowed for a detailed analysis of model transport and composition processes. As well as all of the chemical and aerosol fields, fluxes through all chemical reactions and deposition processes were output as monthly means. Model restart files were also saved to allow for rerunning short sections with an increased (and higher-frequency) output request for comparison against flight campaigns. Updates to the experiments were made throughout the project, incorporating bugfixes and model improvements. The simulations performed are listed in Table 6.

Model integrations were performed using a nudged (Telford et al., 2008) configuration of the UKESM1 (Seljar et al., 2019) at Unified Model version 11.5. For nudged-model integrations, the horizontal wind fields and potential temperature are relaxed to either the ERA-Interim (Dee et al., 2011) or ERA5 (Hersbach et al., 2020) datasets using an *e*-folding relaxation timescale of 6 h. Sea-surface temperatures and sea-ice fields were prescribed from the Reynolds dataset (Reynolds et al., 2002). UKESM simulations were performed using the StratTrop chemical scheme which simulates the O_x, HO_x, and NO_x chemical cycles and the oxidation of carbon monoxide, ethane, propane, and isoprene in addition to chlorine and bromine chemistry, including heterogeneous processes on polar stratospheric clouds (PSCs) and liquid sulfate aerosols (SAs). The two-moment GLOMAP-mode aerosol scheme from the United Kingdom Chemistry and Aerosols (UKCA) model (Mulcahy et al., 2020) is used to simulate sulfate and secondary organic aerosol (SOA) formation and is driven by prescribed oxidant fields. For further details on the UKESM chemistry and aerosols scheme, the reader is referred to Archibald et al. (2020). Simulations were performed from 1981 to 2014 using CMIP historical forcings (labelled as HIST) and continued until 2019 (ERA-Interim) or 2020 (ERA5) using Shared Socioeconomic Path-

Figure 5. Long-term measurements of methane from PPAO, showing a strong long-term increase.

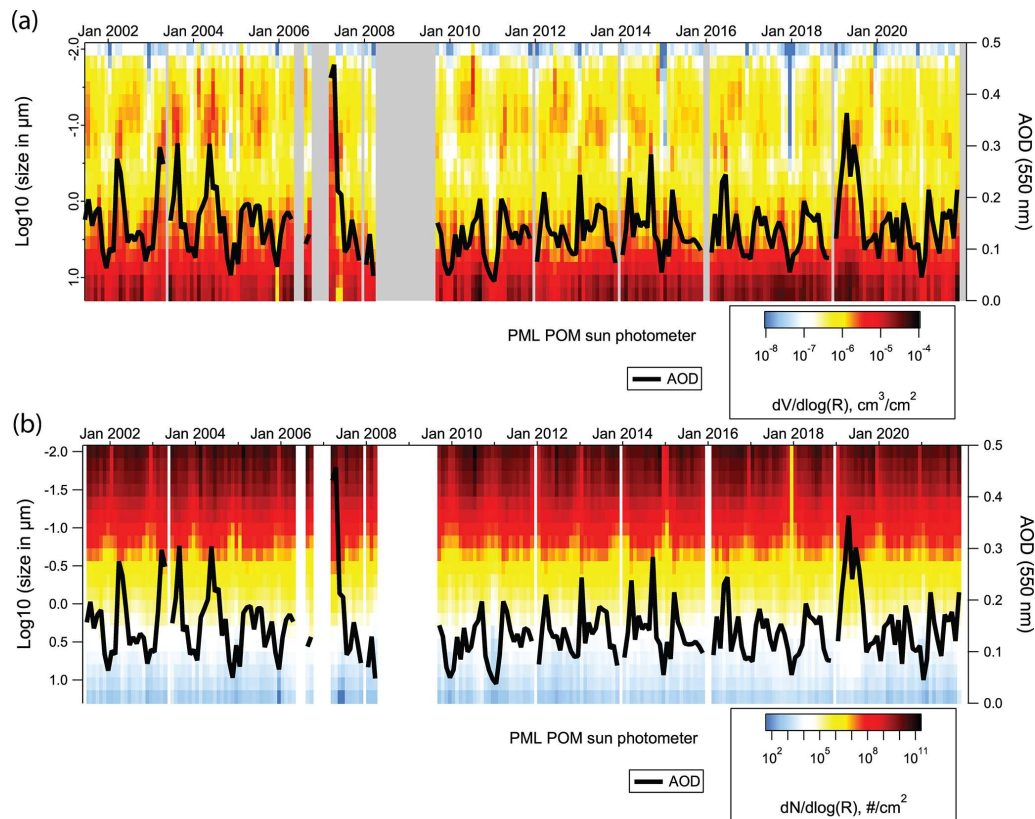

Figure 6. Long-term aerosol observations from the PML rooftop (monthly mean) showing the (a) volume distribution and (b) number distribution. The thick black line shows the aerosol optical depth (AOD).

ways (SSP) scenario SSP3-7.0 forcings (labelled as SCEN), as per the AerChemMIP experiment definition (Collins et al., 2017); see Table 6 for details.

In order to identify the impact of transport on modelled tropospheric ozone in the North Atlantic, two sets of diagnostic tracers were defined.

First, four different stratospheric ozone tracers (O_3S) were added. These are constrained in the stratosphere and evolve freely in the troposphere where they follow equivalent loss

processes to the prognostic ozone field simulated by the model. The four O_3S tracers are described below:

1. Stratospheric concentrations are set to the prognostic ozone field above a model-diagnosed tropopause defined by the 2PV+380K surface.
2. Stratospheric concentrations are fixed at 1 ppmv above a model-diagnosed tropopause defined by the 2PV+380K surface.

3. Stratospheric concentrations are set to the prognostic ozone field above a model-diagnosed tropopause defined by the World Meteorological Organization (WMO) tropopause definition.
4. Stratospheric concentrations are fixed at 1 ppmv above a model-diagnosed tropopause defined by the WMO tropopause definition.

Tracers 1 and 3 are similar to the O_3_S tracers used in the Chemistry Climate Model Initiative (CCMI) experiments (Abalos et al., 2020) and represent tropospheric ozone originating from the stratosphere, while tracers 2 and 4 (also referred to as constant O_3_S tracers or O_3_{S-C}) give a complementary measure of downward transport from the stratosphere that is not affected by the stratospheric ozone geographical distribution or trends (Russo et al., 2023). An example of a tracer-1 tropospheric column and its seasonal variation is given in Fig. 7a–d.

Second, 30 regionally emitted tracers were included to diagnose long-range transport into the North Atlantic region. These have a lifetime of either 5 or 30 d, and emission regions are sketched in Fig. 7e.

2.4.1 Data archive

A total of 892 Tb of UKESM1 model data was generated through the ACSIS project. A huge number of model diagnostics were output, including high-temporal-frequency fields (hourly) across the North Atlantic Basin. These are listed here at <https://www.ukca.ac.uk/wiki/index.php/AC SIS/u-bv711/STASH> (last access: 19 December 2024). Owing to the large nature of the model dataset, selected core chemical species and tracers are available for download as monthly mean files from the CEDA dataset <https://data.ceda.ac.uk/badc/acsis/UKESM1-hindcasts> (Abraham, 2024). These include ozone and ozone precursors (O_3 , NO , NO_2 , CO , and methane) and the idealized tracers used to diagnose transport in the North Atlantic (4 stratospheric tracers and 30 regionally emitted tracers). These data are available for all of the model runs described in Table 6. The data are in Met Office PP format, which can be read using open-access Python libraries (Python cf package) held at <https://ncas-cms.github.io/cf-python> (last access: 19 December 2024). If desired, users may also apply for a Met Office MASS (offline tape archive) account at the UK JASMIN data facility (<https://jasmin.ac.uk>, last access: 19 December 2024) and search the Rose suite IDs given in Table 6 for access to data from the specific experiments performed.

3 Ocean datasets

The North Atlantic Ocean is a major component of the overall North Atlantic climate system, and one of the key objectives of the ACSIS programme was to document the significant changes in ocean circulation and heat content which

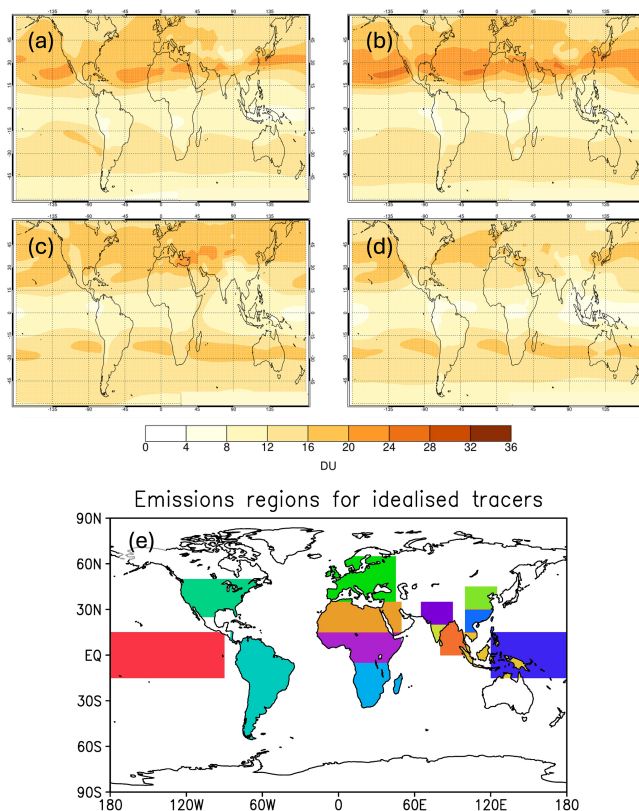

Figure 7. Integrated tropospheric column O_3_S tracer (in Dobson units, DU) defined using prognostic ozone and the 2PV+380K tropopause, averaged over 2005–2017 using HIST1 and SCEN1 simulations (see Table 6 for details) for (a) December–January (DJF), (b) March–May (MAM), (c) June–August (JJA), and (d) September–November (SON). (e) Emission regions for the 5 and 30 d regional tracers.

have taken place since the middle of the 20th century, to investigate the physical processes responsible, and to identify their external drivers. Another objective was to understand how the ocean might change in the next several decades and to evaluate the potential impacts of these changes on human society and activities. In order to fulfil these objectives, we compiled a substantial number of new data products and new model simulations.

The data products were compiled on the underlying principle of estimating components of the North Atlantic heat budget plus the sea-surface temperature and sea-surface height (dynamic and thermosteric), as these latter two are key to the wider impacts of the ocean on the atmosphere and on coastal sea level. Thus, we brought together a new water-mass-preserving, objectively interpolated ocean temperature and salinity dataset based on the international Argo float array described in Sect. 3.1 (King, 2023) with two basin-scale observational estimates of the horizontal ocean volume and heat transports at $26^\circ N$ and at $\sim 55^\circ N$ described in previous publications (RAPID – <https://rapid.ac.uk/rapidmoc/>,

Table 6. Description of the UKESM1 model simulations.

Simulation	Nudging dataset	Time period	Notes	Rose suite ID
HIST1	ERA-Interim	1981–2014	Settings as per UKESM1	u-bv711 (Jan 1981–Nov 1991) and u-bw316 (Dec 1991–Dec 2014)
HIST2	ERA5	1982–2014	Includes code-changes described in Ranjithkumar et al. (2021)	u-bw784 (Jan 1982–Dec 2014)
HIST3	ERA5	1982–2014	Includes code-changes described in Ranjithkumar et al. (2021), technical improvements to the top-boundary condition of the tracers, updated photolysis rates, and the improved heterogeneous chemistry of Dennison et al. (2019)	u-bv828 (Jan 1982–May 2008) and u-bx320 (Jun 2008–Dec 2014)
SCEN1	ERA-Interim	2015–2019	Continuation of HIST1	u-by117 (SSP3-7.0)
SCEN2	ERA5	2015–2020	Continuation of HIST2	u-by803 (SSP3-7.0)
SCEN3	ERA5	2015–2020	Continuation of HIST3	u-by808 (SSP3-7.0)

McCarthy et al., 2015, and Moat et al., 2020, 2022; and OS-NAP – <https://www.ukosnap.org>, Lozier et al., 2019) and a new high spatial and temporal resolution Atlantic sea-surface temperature dataset previously described by Williams and Berry (2020). On the modelling side, we undertook new cutting-edge NEMO-forced ocean model simulations with a variety of surface forcing datasets at resolutions of $1/4$ and $1/12^\circ$, described in Sect. 3.2, complementary to similar coupled ocean–atmosphere integrations performed at both high and low atmospheric resolution (previously published and described as an additional dataset in Sect. 5.2).

3.1 Ocean temperature and salinity and the upper-ocean heat content

In order to understand and quantify decadal climate variability and trends in the North Atlantic region, the NOC has produced new ocean temperature and salinity datasets based on the Argo float array using objectively mapped Argo profiles based on density levels, which preserve ocean water masses (Desbruyères et al., 2017). The dataset covers the period from 2004 to present and extends to depths of up to 2000 m. Two versions are available with spatial resolutions of 2 and 1° respectively. During ACSIS, the main use of this dataset has been to calculate the subtropical and subpolar heat content alongside other available estimates in order to understand the interannual to decadal variability in the North Atlantic heat budget (Fig. 8).

Here, we illustrate the subpolar ocean heat content (SOHC), which is an indicator of long-term changes in the heat supply to the North Atlantic region (Fig. 9). Changes in the SOHC are thought to be important precursors of Atlantic Multidecadal Variability (e.g. Sutton et al., 2018) and have been linked to changes in climate extremes – for example, the number of Atlantic hurricanes (Dunstone et al.,

Figure 8. Subpolar ocean heat content index (in units of 10^{22} J) using EN4 (black) and Argo OI (red) for (a) 1950–2020 and (b) during the Argo period (2004–2020). Thick lines have a low-pass filter applied with variability on periods shorter than 1.8 years removed.

2011). The ACSIS SOHC time series are integrated from the region between 45 and 67° N and between 80° W and 0° E. The time series are calculated from gridded EN4.2.2 (Good et al., 2013) and Argo objectively mapped $1^\circ \times 1^\circ$ temperature datasets (King, 2023). The SOHC calculated from the new dataset developed during ACSIS is shown in red (based only on Argo measurements), while another calculation using the standard Met Office EN4 product (based on Argo, hydrographic, and remote-sensing measurements) is shown in black. The two datasets agree well over the overlapping period from 2004 to present, and the differences between the decadal filtered lines give a useful indication of the uncertainty in the heat content estimates due to the method

of calculation. This dataset can be used in conjunction with RAPID and OSNAP as well as with the new Williams and Berry (2020) sea-surface temperature (SST) dataset mentioned in the introduction to this section.

3.1.1 Data archive

Objectively mapped temperature and salinity data and are available for download from the British Oceanographic Data Centre (BODC) as self-describing NetCDF (<https://doi.org/10.5065/D6H70CW6>, NSF Unidata, 2023) files: <https://doi.org/10.5285/fe8e524d-7f04-41f3-e053-6c86abc04d51> (King, 2023). BODC also provides upper-ocean heat content time series (in NetCDF format): <https://doi.org/10/g6wm> and <https://doi.org/10/g8g2> (Moat et al., 2021a–b).

3.2 Forced ocean-ice simulations

Multiple forced ocean-ice simulations were run under ACSIS in order to elucidate the mechanisms of variability seen in the observations (e.g. Fig. 8). A particular emphasis was placed on understanding how uncertainty in surface forcing (meteorological conditions, such as wind stress and air temperature) impacts predictions of climatically important processes such as the AMOC (Sect. 3.2.1). Another focus was on understanding the impact of modelling at higher (eddy-resolving/eddy-rich) horizontal resolution on the simulated ocean variability and trends compared with using a standard (eddy-permitting) resolution (Sect. 3.2.2).

3.2.1 The 1/4° ocean models forced with three different surface meteorological datasets

Three integrations of a global-ocean and sea-ice configuration, consisting of Global Ocean v6 (GO6; Storkey et al., 2018) and Global Sea Ice v8.1 (GSI8.1; Ridley et al., 2018), were carried out to provide a tool for scientific investigation of the mechanisms of variability in the AMOC and other modes of variability in the Atlantic Ocean. GO6 is based on NEMO v3.6 (Madec et al., 2016), whereas GSI8.1 is based on CICE v5.2.1 (Hunke et al., 2013; Ridley et al., 2018). The GO6 ocean configuration was chosen to be the same as that developed under the Joint Marine Modelling Programme (JMMP; <https://www.metoffice.gov.uk/research/approach/collaboration/joint-marine-modelling-programme>, last access: 19 December 2024) as the ocean component of the UK's submissions under CMIP6, namely GC3.1 (Williams et al., 2017) and UKESM1 (Sellar et al., 2019), and informed choices made in the UK Ocean Model Intercomparison Project (OMIP; Griffies et al., 2016) integrations. Three forcing datasets were used to assess the sensitivity of the models to the choice of forcing data. These were the CORE2 (Large and Yeager, 2009), DFS5.2 (Brodeau et al., 2010), and JRA-55 (Tsujino et al., 2018) datasets, each supplying

gridded surface meteorological variables (air temperature, humidity, and surface winds at subdaily intervals), surface radiative fluxes (downwelling shortwave and longwave radiation at daily intervals), and freshwater input (snow and precipitation at monthly intervals).

The simulations were run on a global domain on the eORCA025 1/4° grid, with 75 vertical levels. The integrations were run from 1958 to 2007 (CORE2), from 1958 to 2015 (DFS5.2), and from 1958 to 2020 (JRA-55), and monthly means are archived. Variables archived include full-depth potential temperature and salinity; horizontal and vertical velocity components; surface fluxes of heat, freshwater, and momentum; mixed-layer depth; and sea-ice cover and thickness. However, many other state and process variables were also archived. Note that sea-ice files from the JRA-forced run are only available for the years 1990–2001 and 2002–2020. These forced ocean-ice simulations use the same configuration as the ocean component of the coupled simulations described in Sect. 5.2.

A comparison of the model drifts in globally averaged temperature and salinity is shown in Fig. 9. The reason for showing model drifts is to alert users to the magnitude and sign of biases present in these model simulations. Biases exist in all model simulations and must be taken into account when using them to understand historical ocean circulation changes. There is a large positive drift in upper-ocean salinity in the DFS5.2-forced simulation (Fig. 9e) and a relatively large freshening in the CORE2 simulation (Fig. 9d). Overall, the JRA-55-forced simulation shows moderate drift in both variables (Fig. 9f). Thus, this ensemble is suitable for understanding the impact of model biases on the representation of historical ocean circulation variability. For example, simulated interannual to multidecadal changes in the Atlantic Ocean circulation are similar between the models despite differences in the mean surface temperature and salinity (Fig. 10). More details on the three simulations, including their AMOC variability, are given by Megann et al. (2021a).

3.2.2 The 1/4° and 1/12° “twin” simulations

Two integrations of the Global Ocean v8p7 (GO8p7) ocean and sea-ice configuration simulation were run under the ACSIS programme. This is based on NEMO v4.0.4 (Madec et al., 2019), including the SI3 sea-ice model, and has been developed under the JMMP (see <https://www.metoffice.gov.uk/research/approach/collaboration/joint-marine-modelling-programme>, last access: 19 December 2024). The simulations are identical apart from the ocean horizontal resolution: one uses a 1/4° grid, whereas the other uses a 1/12° grid. They are forced with the JRA-55 surface forcing dataset (Tsujino et al., 2018) from 1958 to 2021. The integrations are intended to provide a tool for scientific investigation of the mechanisms of variability in the AMOC and ocean heat content of the Atlantic Ocean at an eddy-rich resolution. The GO8p7 configuration is close

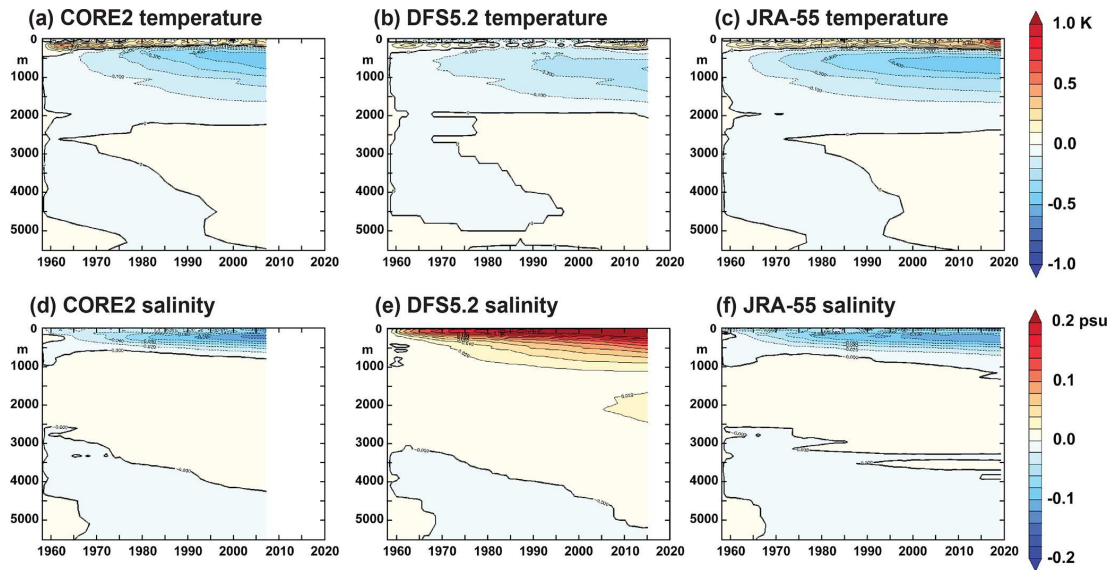

Figure 9. Annual drifts in global mean (a–c) temperature (K) and (d–f) salinity (psu – practical salinity units) as a function of depth in simulations forced with the ACSIS $1/4^\circ$ ocean model. Panels (a) and (d) are from the CORE2-forced simulation, panels (b) and (e) are from the DFS5.2-forced simulation, and panels (c) and (f) are from the JRA-55-forced simulation.

Figure 10. AMOC time series (Sv) for 1960–2020 from simulations forced with the ACSIS $1/4^\circ$ ocean model at (a) 26° N and (b) 45° N. Time series from all three integrations are shown in each panel: CORE2-forced simulation (black); DFS5.2-forced simulation (red); and JRA-55-forced simulation (green). The AMOC derived from observations at 26° N (the RAPID-MOCHA array), available from 2004 onwards, is plotted in cyan in panel (a).

to that expected to be incorporated in the GC5.1 coupled climate model and the UKESM2, both aimed at CMIP7. The configuration was implemented at the two resolutions, with the parameter and physics setting as close as possible (there are some necessary changes to lateral friction which are required for numerical stability at a higher resolution), to investigate the sensitivity of the circulation, numerical mixing, and other metrics to the resolution.

As in Sect. 3.2.1, the integrations were carried out on a global domain on eORCA025 $1/4^\circ$ and eORCA12 $1/12^\circ$ grids, with 75 vertical levels. The integrations were run from 1958 to 2021, and monthly and annual means of the 3D and 2D model fields were saved (including full-depth potential temperature and salinity; horizontal and vertical velocity

components; surface fluxes of heat, freshwater, and momentum; mixed-layer depth; and sea-ice cover and thickness). The 5 d means of a selection of surface fields (including SST, mixed-layer depth, and sea-surface height) are also archived.

To illustrate the simulations, we show time series of some key globally integrated variables from the twin simulations as well as (for context) from the three $1/4^\circ$ simulations already described in Sect. 3.2.1 (Fig. 11). Global mean temperature drifts are of the order of 0.05 K over the ~ 50 -year integrations (or 0.001 K yr^{-1}). The $1/12^\circ$ simulation has a smaller drift than its twin $1/4^\circ$ resolution. The twin simulations show a positive temperature drift, whereas the other simulations show a negative drift. We expect to see an SST warming trend under the influence of anthropogenic warm-

ing superimposed on interannual and decadal variability. All of the simulations show strong interannual variability with about the same amplitude and timing, forced by interannual changes in wind stress and buoyancy forcing, and not influenced by global temperature and salinity drifts. On decadal and longer timescales the difference between variability, secular trends, and model drifts can be blurred. The models all show a small reduction in global mean SST from initialization to the late 1970s. The DFS5.2-forced simulation then continues to reduce its SST until the mid-1980s, after which the SST remains more or less stable until about 2010; however, all of the other simulations increase their SST at a fairly steady rate throughout the 1980s, 1990s, and 2000s. From about 2010 onwards, all of the simulations experience strong surface warming. Globally integrated downward net surface heat flux (sum of turbulent and radiative components) is consistent with the global mean surface temperature evolution with a negative net surface flux in the early decades for the three simulations with different surface flux forcing and a positive net flux for the twin simulations. The net heat flux for the twin simulations is generally positive, whereas it only becomes positive around the year 2000 for the other simulations, and this is when the global mean temperature in those simulations starts to rise. The downward heat flux clearly shows the signals of large volcanic eruptions (Agung in 1964, El Chichón in 1982, and Pinatubo in 1991) as well as the 1997 El Niño event (see Balmaseda et al., 2013). The sharp downward dip in 2009 is interesting and possibly linked to the sudden AMOC reduction at that time, but further research is required to investigate this. With the exception of the DFS5.2-forced simulations, global mean salinity and global mean surface salinity show quite small trends consistent with a reasonably balanced surface freshwater flux. The DFS5.2-forced simulation shows strong salinification consistent with a net loss of freshwater through the surface. The twin runs show the best conservation of freshwater. Finally, the net heating/cooling and freshening/salinification of the simulations is reflected in the global mean sea-surface height, which is most stable in the twin simulations.

A final illustration shows the mean surface circulation in the North Atlantic from the twin simulations (Fig. 12). The most obvious difference in the surface current speed (Fig. 12a, b) is that the Gulf Stream separation is more realistic in the 1/12° simulation, in which the current moves northeastwards off Cape Hatteras (~38° N). This contrasts with the 1/4° simulation, in which the current shifts direction anticlockwise to remain quite close to the coast. The kink in the Gulf Stream Extension at the northwestern corner (40° N, ~50° W) is also more realistic in the 1/12° simulation; moreover, there is a discernible signature of the Azores Current (zonal feature around 34° N), which is extremely faint in the 1/4° simulation. Similar features can be seen in the mean sea-surface height from the two simulations (Fig. 12c, d). One interesting difference is in the penetration of the Labrador Current much further south in the 1/12° sim-

ulation – where the low sea-surface heights characteristic of the subpolar gyre penetrate southwest along the North American shelf/slope region north of the Gulf Stream Extension (between 35 and 45° N and between 80 and 50° W). Decadal variability in the position of the Gulf Stream has been shown to be linked to salinity anomalies that are advected southwards by the Labrador Current (New et al., 2021); therefore, these differences between the simulations are likely to impact their simulation of AMOC variability.

3.2.3 Data archive

Data from all of the ocean simulations are archived in NetCDF format, with four separate files for each month of simulation. Variables in NEMO are divided into four types that are discretized on slightly different numerical grids, known as the *T* grid for tracers (such as temperature and salinity) and the *U*, *V*, and *W* grids for the corresponding components (positive eastward, northward, and upward respectively) of the 3D velocity (Madec et al., 2016, 2019). Each variable has a long name that gives a detailed description of the variable (see Madec et al., 2016, 2019 for an explanation of the data output format). Separate monthly NetCDF files contain sea-ice variables on the CICE grid and Lagrangian iceberg properties and trajectories. The data are archived at CEDA (Megann et al., 2021b, c, d):

- CORE2-forced run – <https://doi.org/10.5285/119a5d4795c94d2e94f610647640edc0> (Megann et al., 2021b);
- DFS5.2-forced run – <https://doi.org/10.5285/a0708d25b4fc44c5ab1b06e12fef2f2e> (Megann et al., 2021c);
- JRA-55-forced run – <https://doi.org/10.5285/4c545155dfd145a1b02a5d0e577ae37d> (Megann et al., 2021d);
- 1/4° twin simulation – <https://doi.org/10.5285/e02c8424657846468c1ff3a5acd0b1ab> (Megann et al., 2022a);
- 1/12° twin simulation – <https://doi.org/10.5285/399b0f762a004657a411a9ea7203493a> (Megann et al., 2022b).

4 Ice datasets

4.1 Advanced sea-ice model simulations

Results from six forced ocean-ice simulations and two stand-alone ice simulations are included to document the impact of sea-ice physics and atmospheric forcing data on the Arctic sea-ice evolution. All of them use the same sea-ice model CICE configuration GSI8.1 (Ridley et al., 2018), and the ocean-ice simulations use the same ocean model NEMO

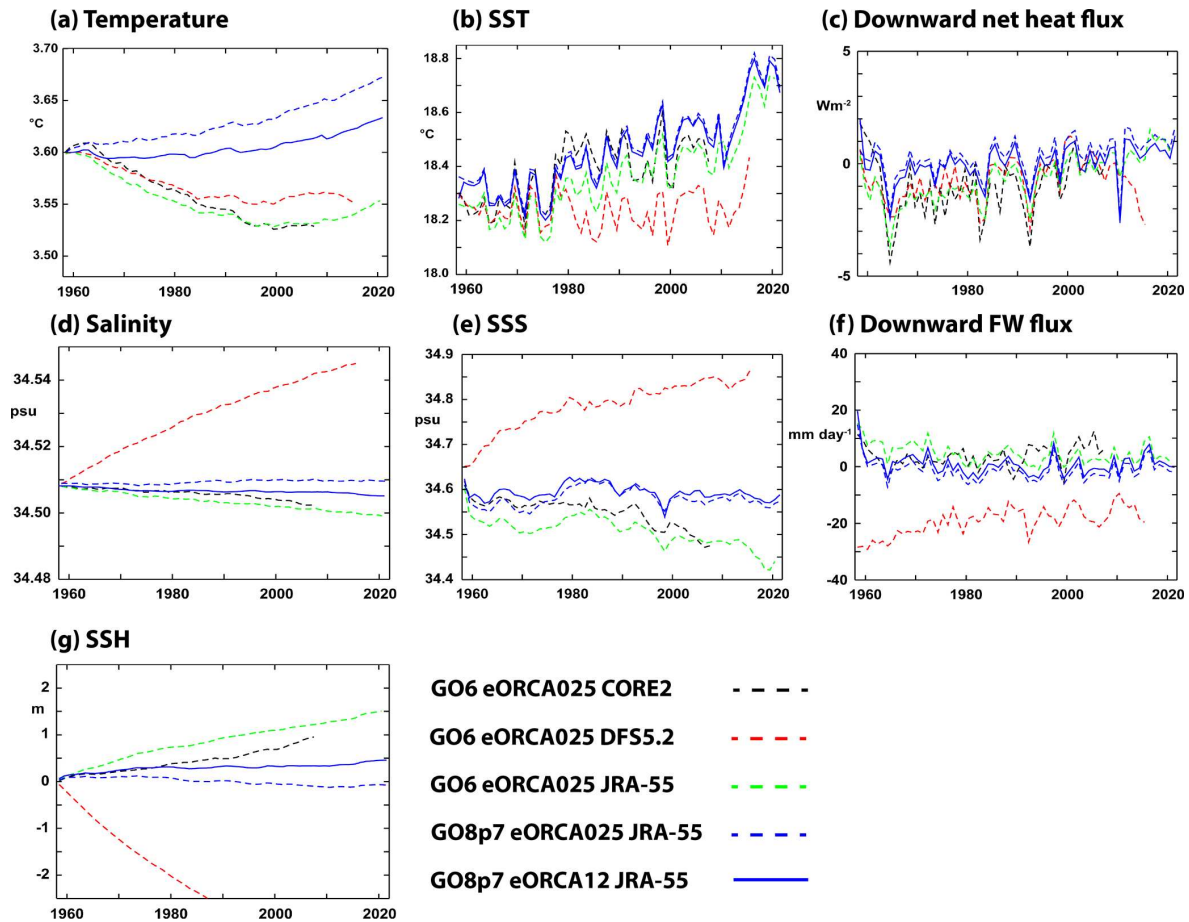

Figure 11. Time series of key variables in simulations forced with the ACSIS 1/4 and 1/12° ocean model. The variables plotted are as follows: **(a)** global mean temperature; **(b)** global mean sea-surface temperature; **(c)** global mean net downward air–sea heat flux; **(d)** global mean salinity; **(e)** global mean sea-surface salinity; **(f)** downward freshwater flux; and **(g)** global mean sea-surface height. Dashed lines are from the 1/4° model (CORE2-forced simulation – black; DFS5.2-forced simulation – red; JRA-55-forced, 1/4° twin simulation – blue), whilst the solid blue line is from the 1/12° twin simulation. Note that the green and blue lines are all from JRA-55-forced model simulations but with different model code versions and configurations (see text).

GO6.0 (Storkey et al., 2018) as the forced ocean-ice simulations of Sect. 3.2 and the HadGEM3 climate model of Sect. 5.2. Three different atmospheric forcing datasets are applied: NCEP Reanalysis-2 (NCEP2) data (Kanamitsu et al., 2002, updated 2020), CORE2 surface data (Large and Yeager, 2009), and the DFS5.2 atmospheric forcing dataset (Dussin et al., 2016). Regarding the sea-ice component, we use the default CICE setup as in HadGEM3 (CICE-default) and an advanced setup (CICE-best) in which a new process is added (snow loss due to drifting snow) and some adjustments have been made to model physics and parameters. See Schröder et al. (2019) and Table 7 for details.

The impact of our changes to the sea-ice model on the fidelity of the model sea-ice simulation is shown in Fig. 13. All simulations with the default CICE setup (thin lines) underestimate the mean Arctic sea-ice thickness during winter. Figure 13 shows that the mean Arctic CryoSat-2 sea-ice thickness is more than 50 cm thicker in April than in those

simulations (see Sect. 5.3 for the source of our ice thickness estimates). By applying the advanced CICE setup, all simulations (stand-alone, NEMO-CICE 1°, and NEMO-CICE 1/4°; thick lines) show realistic mean April sea-ice thickness. The advanced setup also leads to improvements in simulating summer sea-ice extent (not shown) and highlights the importance of sea-ice physics for accurate model simulations for the Arctic.

4.2 Data archive

Data from the global-ocean simulations with advanced sea ice are archived in NetCDF format, as described in Sect. 3.2.3. Stand-alone sea-ice simulations are similar, but output consists of a single NetCDF file containing sea-ice variables on the CICE grid for each month of simulation. The data are accessible via CEDA: <http://catalogue.ceda.ac>.

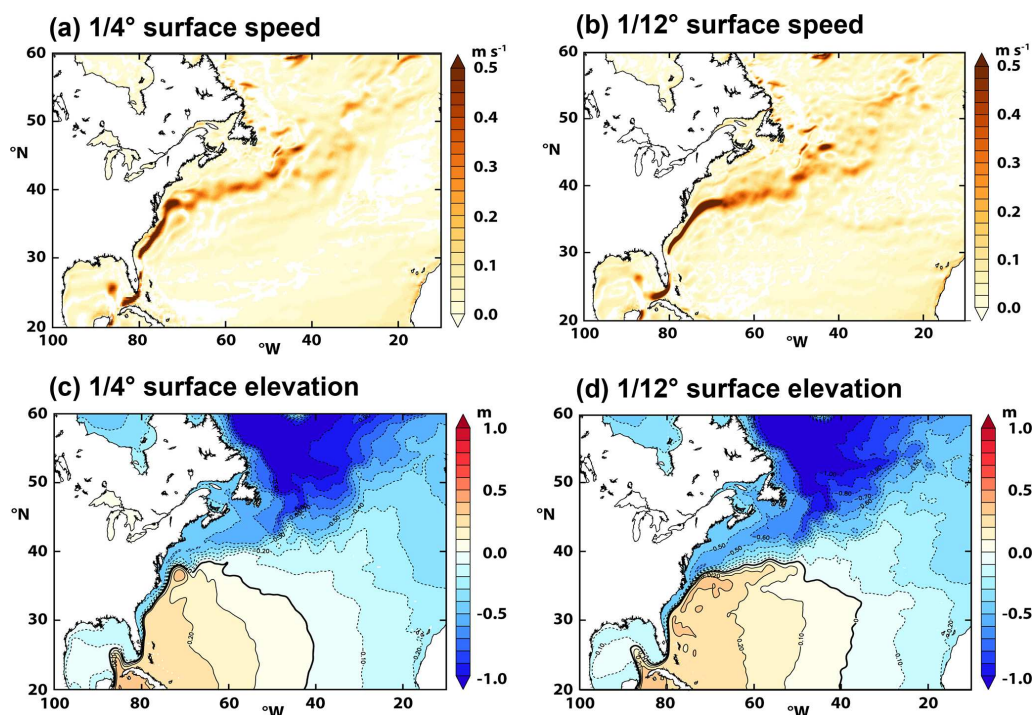

Figure 12. Surface North Atlantic circulation from the ACSIS GO8p7 twin simulations averaged over years from 2000 to 2009. Surface speed (in m s^{-1}) for (a) the $1/4^\circ$ simulation and (b) the $1/12^\circ$ simulation and sea-surface height (in m) for (c) the $1/4^\circ$ simulation and (d) the $1/12^\circ$ simulation. In panels (c) and (d), the global mean surface height has been subtracted to make comparison easier.

uk/uuid/770a885a8bc34d51ad71e87ef346d6a8 (see Megann et al., 2021e).

5 Synergies with previously published work

The new datasets described in the previous sections should be viewed in the context of (and potentially used in conjunction with) several other datasets generated in whole or in part by the ACSIS programme and already published and described in the scientific literature. Here, we provide a very brief overview of these other datasets and include links to where they can be accessed. The subsections below correspond to the preceding sections on atmospheric composition (Sect. 5.1, corresponding to Sect. 2), ocean observations and model simulations (Sect. 5.2, corresponding to Sect. 3), and sea-ice model simulations (Sect. 5.3, corresponding to Sect. 4).

5.1 Stratospheric aerosol surface area density from explosive volcanic eruptions

The MajorVolc datasets are model simulations within the high-top N96L85 GA4 UM-UKCA composition–climate model (Walters et al., 2014) of the monthly progression of the volcanic aerosol clouds from the three largest volcanic eruptions of the 20th century – Agung in 1963, El Chichón in 1982, and Pinatubo in 1991. The latter two eruptions fell

within the period covered by the UKESM simulations described in Sect. 2.4 and, thus, could be useful in interpreting the aerosol distributions in those simulations. The simulations are based on the Historical Eruption SO_2 Emission Assessment (HErSEA) experiment protocol (Timmreck et al., 2018). They apply v8.2 of the GLOMAP-mode aerosol microphysics module (Mann et al., 2010; Dhomse et al., 2014; Mann et al., 2015; Brooke et al., 2017; Dhomse et al., 2020) and improve on the CMIP6 volcanic aerosol dataset (Arfeuille et al., 2014; Luo, 2016). The datasets are described by Dhomse (2020). Dataset identifiers are as follows: <https://doi.org/10.17632/n3g2htz9hk.1> (Dhomse, 2020) and <https://doi.org/10.5281/zenodo.4739170> (Feng et al., 2021) for Pinatubo; <https://doi.org/10.5281/zenodo.4744633> (Dhomse et al., 2021a) for El Chichón; and <https://doi.org/10.5281/zenodo.4744686> (Dhomse et al., 2021b) for Agung.

5.2 CMIP6 HighResMIP global climate model simulations

All of the model- and observation-based datasets described in Sects. 2–4 may be placed in the context of Phase 6 of the Coupled Model Intercomparison Project (CMIP6) HighResMIP (<https://www.highresmip.org/>, last access: 19 December 2024) subproject (Haarsma et al., 2016; Roberts et al., 2018, 2019). The UK contribution to this subproject was based on the HadGEM3 global climate

Table 7. Overview of model simulations with default and improved sea-ice processes.

Simulation	Atmospheric forcing	Ocean model	CICE setup	Time period
CICE-default	NCEP2	Mixed layer	CICEv5.1.2 with a prognostic melt pond model and elastic–anisotropic–plastic (EAP) rheology	1980–2020
CICE-best	NCEP2	Mixed layer	Same as the CICE-default but with several modifications, including a snow drift scheme, bubbly conductivity scheme, increased sea-ice emissivity, and reduced melt pond max fraction parameter (see Schröder et al., 2019)	1980–2020
NEMO-CICE-1deg-default-CORE	CORE II	NEMOv3.6	CICEv5.1.2 with a prognostic melt pond model	1960–2009
NEMO-CICE-1deg-best-CORE	CORE II	NEMOv3.6	Same as CICE-best	1960–2009
NEMO-CICE-1deg-best-DFS	DFS5.2	NEMOv3.6	Same as CICE-best	1960–2015
NEMO-CICE-1deg-best-NCEP	NCEP2	NEMOv3.6	Same as CICE-best	2000–2020
NEMO-CICE-1/4deg-default-DFS	DFS5.2	NEMOv3.6	CICEv5.1.2 with a prognostic melt pond model	1979–2015
NEMO-CICE-1/4deg-best-DFS	DFS5.2	NEMOv3.6	Same as CICE-best but with increased ice and snow conductivity instead of a snow drift scheme	1979–2015

model (Hewitt et al., 2011), with a resolution of ~ 50 km in the atmosphere and $\sim 0.25^\circ$ in the ocean, and was delivered as part of the EU Horizon 2020 PRIMAVERA project (<https://www.primavera-h2020.eu/>, last access: 19 December 2024). The NEMO ocean component in these simulations is the same configuration as the forced ocean model simulations described in Sect. 3.2. The HadGEM3 PRIMAVERA simulations most relevant to this paper were atmosphere-only simulations with horizontal resolutions of N256 (~ 50 km; <http://doi.org/10.22033/ESGF/CMIP6.6029>, Roberts, 2017a; <http://doi.org/10.22033/ESGF/CMIP6.6013>, Roberts, 2019a) and N512 (~ 25 km; <http://doi.org/10.22033/ESGF/CMIP6.6024>, Roberts, 2017b; <http://doi.org/10.22033/ESGF/CMIP6.6008>, Roberts, 2019b) and analogous fully coupled simulations with an ocean resolution of $1/4^\circ$ (<http://doi.org/10.22033/ESGF/CMIP6.6040>, Roberts, 2018a; <http://doi.org/10.22033/ESGF/CMIP6.5984>, Roberts, 2019c; <http://doi.org/10.22033/ESGF/CMIP6.6041> and <http://doi.org/10.22033/ESGF/CMIP6.5985>, Schiemann et al. 2019a, b). The simulations were conducted in pairs consisting of a historical simulation from 1950 to 2014 and a future simulation from 2015 to 2050. Two further cutting-edge simulations were performed at even higher resolution in both the ocean and atmosphere, at $1/12^\circ$ and ~ 25 km (N512) respectively

(<https://doi.org/10.22033/ESGF/CMIP6.5881>, Roberts, 2018b; <https://doi.org/10.22033/ESGF/CMIP6.1822>, Coward and Roberts, 2018). The first was a control 1950s climate running from 1950 to 2014, whereas the second was a future simulation (SSP5-8.5) from 2015 to 2050. Roberts et al. (2020) provide an assessment of the simulated AMOC in this and other HighResMIP simulations.

5.3 Ice observations

Pan-Arctic sea-ice thickness is estimated using satellite data from the European Space Agency (ESA) CryoSat-2 (CS2) mission. Launched in 2010, CryoSat-2's main payload is a Ku-band radar altimeter (SIRAL) that measures the elevation of Earth's surface. Sea-ice freeboard (the portion of an ice floe above the waterline) is measured by differencing the elevation of the sea-ice floe and that of the surrounding ocean. Sea-ice freeboard is then converted to thickness by assuming that sea ice floats in hydrostatic equilibrium in the ocean and by assuming values for snow depth and for snow, ice, and ocean density. CryoSat-2's orbit repeats every ~ 30 d, providing Arctic-wide sea-ice thickness estimates every month from October to April. The method and dataset are detailed in full in Tilling et al. (2018), and monthly sea-ice thickness data, gridded at 5 km, are available from the CPOM data por-

Figure 13. Mean April Arctic sea-ice volume per grid cell area over the red region shown in the inset for several model simulations in comparison with CryoSat-2 estimates. CryoSat-2 thickness values are multiplied by the sea-ice concentration from the Special Sensor Microwave/Imager (SSM/I) using the NASA-Team Bootstrap algorithm (Comiso, 2017). The selected region represents the area over which CryoSat-2 data are available for the whole period from 2010 to 2020 (October to April). Table 7 provides more information about the setup of the model simulations.

tal <http://www.cpom.ucl.ac.uk/csopr/sealice.php> (last access: 19 December 2024).

For the purposes of the ACSIS project, we binned individual CryoSat-2 sea-ice thickness estimates provided by CPOM into the five default ice thickness (h) categories of the CICE sea-ice model on a rectangular 50 km grid: (1) $h < 0.6$ m, (2) $0.6 \text{ m} < h < 1.4$ m, (3) $1.4 \text{ m} < h < 2.4$ m, (4) $2.4 \text{ m} < h < 3.6$ m, and (5) $h > 3.6$ m (Schröder et al., 2019). The mean area fraction and mean thickness are then derived for each thickness category. One of the key motivations of binning the CS2 along-track data into sub-grid ice thickness classes is to assess the role of the ice thickness distribution (ITD) in model initialization and to quantify the realism of the CS2 ITD against independent estimates from airborne data. In addition to the bespoke data described above, monthly (October–April 2010–2021) 5 km gridded sea-ice thickness estimates are available (in ASCII and NetCDF formats) on the CPOM data portal: <http://www.cpom.ucl.ac.uk/csopr/sealice.php> (last access: 19 December 2024).

6 Code and data availability

Code availability is not applicable for this article. However, the programs and scripts used for plotting the figures in this article are stored in a Zenodo repository: <https://doi.org/10.5281/zenodo.13972335> (Sinha, 2024). All data have been deposited in reliable data repositories, and access is detailed in Table 1 of this article. The main data sets are as follows:

1. atmospheric composition datasets – <https://doi.org/10.5285/6285564c34a246fc9ba5ce053d85e5e7> (FAAM et al., 2024);

2. ground-based station data – <http://catalogue.ceda.ac.uk/uuid/81693aad69409100b1b9a247b9ae75d5> (National Centre for Atmospheric Science et al., 2010), <https://catalogue.ceda.ac.uk/uuid/8f1ff8ea77534e08b03983685990a9b0> (Plymouth Marine Laboratory and Yang, 2017), and <https://doi.org/10.5285/e74491c96ef24df29a9342a3d57b5939> (Smyth, 2024);
3. model simulations of atmospheric composition – <https://data.ceda.ac.uk/badc/acsis/UKESM1-hindcasts> (Abraham, 2024);
4. ocean heat content diagnostics and gridded temperature and salinity – <https://doi.org/10/g6wm>, <https://doi.org/10/g8g2> (Moat et al., 2021a, b), and <https://doi.org/10.5285/fe8e524d-7f04-41f3-e053-6c86abc04d51> (King, 2023);
5. atmosphere-forced global-ocean sea-ice simulations and stand-alone sea-ice model simulations with advanced sea-ice physics – <http://catalogue.ceda.ac.uk/uuid/770a885a8bc34d51ad71e87ef346d6a8> (Megann et al., 2021e).

7 Summary

We have described the multidisciplinary model and observational datasets that were produced by the UK ACSIS programme and how and where the data can be accessed. The scope of ACSIS was very broad, covering atmospheric composition, atmospheric circulation, ocean circulation, ice sheets (not covered in this paper), sea ice, and their interactions, and this breadth is reflected in the rich variety of

datasets generated. We note that, whilst the focus of the ACSIS programme was the North Atlantic, most of the model products covered the global domain, and many of the observational products have both global and regional significance. Despite its great size and scope, the ACSIS programme had finite resources; thus, it was not able to fully exploit the data it generated. The landmark ACSIS papers cited here can be seen as starting points for further research. Therefore, we believe there is a major opportunity to repurpose our data for new research studies to build on the substantial financial and intellectual investment that ACSIS represents, and we express the hope that the ACSIS datasets provide a lasting legacy to the international environmental science community.

Appendix A: Overview of select aircraft composition instruments

A1 The University of Manchester time-of-flight chemical ionization mass spectrometer

The University of Manchester high-resolution time-of-flight chemical ionization mass spectrometer (UoM ToF-CIMS) is described in detail by Matthews et al. (2023) for aircraft deployment. Briefly, iodide ions cluster with sample gases in the ion–molecule reaction (IMR) region, creating a stable adduct. The flow is then sampled through a critical orifice into the first of the four differentially pumped chambers in the TOF-CIMS, the short-segmented quadrupole (SSQ). Quadrupole ion guides transmit the ions through these stages. The ions are then subsequently pulsed into the drift region of the ToF-CIMS where the arrival time is detected with a pair of microchannel plate detectors with an average mass resolution of 4000 ($m/\Delta m$).

The inlet design is an atmospheric-pressure, rearward-facing, short-residence-time inlet, consisting of 3/8 in. diameter polytetrafluoroethylene (PTFE) tubing with a total length to the instrument of 48 cm. A constant flow of 12 slpm (standard litres per minute) is mass-flow-controlled to the IMR region using a rotary vane pump (Picolino VTE-3). A total of 1 slpm is then subsampled into the IMR for measurement.

An Iris system, as described by Lee et al. (2018), was employed to pressurize and mass-flow-control the sample flow into the instrument, avoiding sensitivity changes that would be associated with variations in pressure in flight that are not controlled sufficiently by the constant-flow inlet. This works upon the principle of the manipulation of the size of the critical orifice in response to changes in the IMR pressure. As with the Lee et al. (2018) design, this works by having a stainless-steel plate with a critical orifice and a movable PTFE plate on top of this, also with a critical orifice. These orifices either align fully and allow maximum flow into the instrument or misalign to reduce flow. This movement is controlled by the 24 V DC output of the IMR

Pirani pressure gauge in relation to the set point and was designed collaboratively with Aerodyne Research Inc. The IMR set point was 72 ± 3 mbar for the aircraft campaigns, which was set through a combination of pumping capacity on the region (Agilent IDP3), mass-flow-controlled reagent ion flow, and sample flow. The reagent ion flow is 1 slpm of ultrahigh-purity (UHP) nitrogen mixed with 2 sccm (standard cubic centimetres per minute) of a pressurized, known-concentration gas mix of CH_3I in nitrogen, passed through the radioactive source (^{210}Po). The total flow through the IMR is measured at the exhaust of the Agilent IDP3 pump, thereby not only monitoring the IMR pressure but also the sample flow. All mass flow controllers and mass flow meters are measured and controlled using the standard Aerodyne Research Inc. EyeOn control unit and software.

A pressure controller is also employed on the SSQ region to make subtle adjustments in this region, independently of any small IMR changes that may occur during flight. This works upon the principle of controlling an electrically actuated solenoid valve in a feedback loop with the SSQ pressure gauge to actively control a leak of air into the SSQ pumping line. The SSQ is pumped using an Ebara PDV 250 pump and held at 1.8 ± 0.01 mbar.

Instrument backgrounds are programmatically run for 6 s every 1 min for the entire flight, by overflowing the inlet with UHP nitrogen at the point of entry into the IMR. Here, a 1/16 in. PTFE line enters through the movable PTFE top plate, ensuring that the flow exceeds that of the sample flow. Inlet backgrounds are also manually run multiple times during campaigns by overflowing as close to the end of the inlet as possible with UHP nitrogen. Data are taken at 4 Hz during a flight and are routinely averaged to 1 Hz for analysis. Of the six points in each background, the first two and the last point are unused, and the mean of the background is calculated using custom Python scripting. Backgrounds are humidity-corrected, and, using linear interpolation, a time series of the instrument background is determined and then subtracted to give the final time series (Matthews, 2023).

A2 The UoM aerosol mass spectrometer

The chemical composition of non-refractory submicron aerosols (organic aerosol – OA; sulfate; nitrate; ammonium; and non-sea-salt chloride – nss-Cl) can be measured by a compact time-of-flight aerosol mass spectrometer (C-ToF-AMS; Aerodyne Research Inc., Billerica, MA, USA) (Drewnick et al., 2005), which provides chemical characterization across a range of ion mass-to-charge (m/z) ratios from 10 to 500. The detailed operation of the AMS, including calibration and correction factors, during aircraft deployment has been described previously (Morgan et al., 2009). In brief, aerosols enter the instrument via an aerodynamic lens inlet, focusing the incoming particles into a narrow beam. The aerodynamic lens system of the AMS in this study is tailored to sample submicron aerosols. Particles exit the aero-

dynamic lens into the particle-sizing chamber, which is evacuated to progressively lower pressures as the particle beam passes through and removes the majority of the gaseous material. Non-refractory components of the particles are then flash-vaporized on a resistively heated porous tungsten surface. The resultant gaseous molecules are ionized by a 70 eV electron beam released from a tungsten filament. These fragment ions are analysed by a time-of-flight mass spectrometer (ToF-MS). The AMS mass spectra were recorded every 8 or 15 s during the ACSIS campaign (AC SIS 1 and ACSIS 3–6). The AMS data were processed using the standard SQUIRREL (SeQUential Igor data RetRiEvaL, v.1.65C) ToF-AMS software package. The AMS data were also calibrated using monodisperse ammonium nitrate and ammonium sulfate particles. A time- and composition-dependent collection efficiency (CE) was applied to the data based on the algorithm by Middlebrook et al. (2012).

A3 The University of York LIF-SO₂

The University of York LIF-SO₂ instrument is a custom-built system for the highly sensitive detection of SO₂ via laser-induced fluorescence and is based on the system originally demonstrated by Rollins et al. (2016). The basic operating principle is the excitation of SO₂ at 216.9 nm, generated from the fifth harmonic of a custom-built tuneable fibre-amplified semiconductor diode laser system at 1084.5 nm, and the subsequent detection of the resultant fluorescence photons. The laser wavelength is rapidly (~ 10 Hz) tuned back and forth between a wavelength which is resonant for SO₂ transition and another which is not resonant for SO₂, with the difference between these signals being directly proportional to the SO₂ concentration within the sample cell. The laser wavelength is tracked using a reference cell containing a known SO₂ concentration.

The ACSIS 7 experiment was part of the first field deployment for the York LIF-SO₂; thus, it was, in part, a learning experience regarding the operation of the instrument aboard an aircraft. The sample flow rate was maintained at 2 slpm, and the use of a ram inlet allowed both the sample and reference cells to be operated at 400 mbar for the full altitude range of the campaign to maximize instrument sensitivity. Multi-point calibrations were carried out across the expected concentration range approximately every 30 min to ensure that the instrument sensitivity was well characterized. To assess (1) the possible quenching effect of excited SO₂ by water vapour or (2) increased wall losses when sampling humid air, calibrations in both stable ambient air and dry zero air were carried out, for which this effect proved negligible. The uncertainty in the LIF-SO₂ measurements was calculated predominantly from the uncertainty in the instrument sensitivity (typically 6%). However, due to inconsistencies in the laser power and laser linewidth, the sensitivity was seen to vary during the course of each flight. Therefore, a mean sensitivity has been applied, and this variation has been

conservatively added to the sensitivity uncertainty on a flight-by-flight basis to give an overall uncertainty of $\sim 15\%$ (using the mean of this variation). The 3σ precision of 225 ppt has also been determined conservatively from stable ambient measurements due to issues with completely overflowing the instrument inlet with zero air during flight.

Author contributions. ATA and BS prepared the original draft of the manuscript with input from TJB, LJC, EM, KR, MRR, FAS, KR, LT, LW, HW, and MY; BS, EM, and MRR edited the original draft; and all authors reviewed the manuscript. SJJ, TJB, EM, CR, FAS, LT, NT, LW, and HW acquired data. ATA, LJC, HC, PE, JL, BS, and MY acquired funding.

Competing interests. The contact author has declared that none of the authors has any competing interests.

Disclaimer. Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims made in the text, published maps, institutional affiliations, or any other geographical representation in this paper. Acknowledgements. The authors gratefully acknowledge financial support provided by the UK Natural Environment Research Council with respect to the extensive data collection efforts during the ACSIS project. Airborne data were obtained using the BAe 146-301 Atmospheric Research Aircraft flown by Airtask Group and managed by the FAAM Airborne Laboratory, jointly operated by UK Research and Innovation and the University of Leeds. We would like to give special thanks to the Airtask Group pilots and engineers as well as all staff at the FAAM Airborne Laboratory for their hard work in helping plan and execute successful flight campaigns during ACSIS. Peter Edwards and Loren Temple were supported by NERC award nos. NE/T008555/1 and NE/S007458/1 regarding the development and operation of the LIF-SO₂. Mingxi Yang, Thomas Bell, and the Penlee Point Atmospheric Observatory measurements were supported by the NERC ACSIS (grant no. NE/N018044/1) and MOYA (grant no. NE/N015932/1) projects. Tim Smyth and the Plymouth sun photometer measurements were supported by the NERC ACRUISE (grant no. NE/S005390/1) project and by the Western Channel Observatory, which is funded by NERC through its National Capability Long-term Single Centre Science Programme, Climate Linked Atlantic Sector Science (grant no. NE/R015953/1). We further thank Frances Hopkins, Jani Pewter, Daniel Phillips, and Simone Louw for instrument maintenance at Penlee Point Atmospheric Observatory. We are also grateful to Luis Neves (Instituto Nacional de Meteorologia e Geofísica, São Vicente – INMG, Mindelo, Cabo Verde) and Shalini Punjabi (WACL) for technical assistance with the CVAO measurements. Model simulations were performed at NCAS, NOC, and CPOM (under ACSIS grant nos. NE/N018001/1 and NE/N018044/1).

Financial support. This research has been supported by the Natural Environment Research Council (grant nos. NE/N018044/1, NE/N018001/1, NE/R015953/1, NE/S005390/1, NE/N015932/1, NE/N018044/1, NE/S007458/1, and NE/T008555/1).

Review statement. This paper was edited by Baptiste Vandecrux and reviewed by two anonymous referees.
