13

14

15 ABSTRACT

16 Thermal stress reduces fertility and fecundity in animals at temperatures below  
17 lethal. Reproductive output is impaired across taxa under diverse heat exposure  
18 regimes, with consequences for individual fitness, population persistence and  
19 ecosystem dynamics. This pattern holds across terrestrial and aquatic systems, with  
20 implications for conservation, livestock, aquaculture and human health. Yet these  
21 sub-lethal effects remain underrepresented in biodiversity forecasts. In this Review,  
22 we synthesize evidence for the biological mechanisms associated with thermally-  
23 induced declines in fertility and fecundity, and assess how life history and exposure  
24 regime shape thermal sensitivity. Fertility-based thermal limits can predict species  
25 distributions and extinction risk better than survival-based measures, although tested  
26 across a limited taxonomic range. Evolutionary responses to fertility loss under  
27 warming appear constrained but increased mutational variation, local adaptation and  
28 hybridization may increase fertility resilience. Key research priorities include broader  
29 taxonomic evaluation of evolutionary potential and ecological outcomes, including  
30 population effects under multiple stressors and impacts on community and  
31 ecosystem dynamics as fertility-sensitive taxa shift range or go extinct. Recognising  
32 and addressing fertility-based vulnerability is essential for anticipating biodiversity  
33 change and designing more effective responses to climate impacts.

## 34 **Introduction**

35 Rising global temperatures are restructuring ecosystems and threatening biodiversity  
36 worldwide. Both the mean and variance in temperature are increasing, with more  
37 frequent and long-lasting extreme weather, including **heatwaves**<sup>1</sup>. While much  
38 attention has focused on lethal impacts of warming<sup>2</sup> reproductive processes are well-  
39 known to be negatively impacted at sub-lethal thermal stress in both sexes<sup>3</sup>. The  
40 thermal range over which **fertility** and **fecundity** (hereafter also referred to  
41 holistically as **reproductive output**) is possible is typically narrower than the survival  
42 range<sup>4</sup> and can fail at temperatures that do not affect survival<sup>5,6</sup>. While fertility and  
43 fecundity are major drivers of population persistence, these non-lethal reproductive  
44 effects remain underrepresented in predictions of species vulnerabilities and  
45 responses to climate change<sup>3</sup>. Recent measures of upper **Thermal Fertility Limits**  
46 (TFLs)<sup>7</sup> (**Box 1**) better match current species ranges and predict temperature-related  
47 extinction<sup>5,6</sup>, and so are likely of critical importance to biodiversity. Moreover, societal  
48 impacts are potentially far-reaching as heat-induced sterility occurs in livestock<sup>8</sup>,  
49 pollinators<sup>9</sup>, and even humans<sup>10</sup> (**Fig. 1**). Thus, the impact of temperature-mediated  
50 effects on fertility and fecundity merit closer examination given the potential to  
51 influence ecosystem services and population persistence, thereby altering species  
52 interactions and community structure.

53

54 In this review, we focus on how elevated temperatures reduce reproductive output by  
55 directly impairing gamete production, fertilisation success, and fecundity. We begin  
56 by outlining patterns of heat-induced reductions in reproductive output, then review  
57 physiological and molecular mechanisms underlying thermal damage to gametes,  
58 fertilisation and fecundity. We highlight factors influencing variation in thermal  
59 impacts on reproduction, such as sex, fertilisation mode, and exposure duration and  
60 how **phenotypic plasticity** may mediate responses. To gauge potential impacts on  
61 biodiversity, we assess the ecological and evolutionary consequences of thermal  
62 limits to fertility, including on predictions of species re-distribution, extinction risk, and  
63 sexual selection and the potential for adaptive evolutionary responses to increased  
64 warming. Finally, we outline research priorities for better predicting the extent to  
65 which thermally-induced reproductive decline will impact biodiversity under ongoing  
66 climate change. Although temperature also alters traits that influence reproductive  
67 success - such as mating behaviour<sup>11</sup>, reproductive timing/ phenology<sup>12</sup> or parental  
68 care<sup>13</sup> – our emphasis is on thermal effects on parental fertility and fecundity.  
69 Temperature can also influence post-fertilisation mortality of embryos or offspring  
70 with experiments frequently not disentangling effects of heat stress on parental  
71 fertility and fecundity from offspring viability<sup>14</sup>. To minimize this problem, we highlight  
72 studies where gametes or parents, rather than embryos or offspring, experienced  
73 heat stress.

74

## 75 **Patterns of heat-induced sterility**

76 Research on thermal impacts on fertility is dominated by terrestrial invertebrates  
77 (particularly insects) and laboratory animal models<sup>14</sup> (**Supplementary Table1**).  
78 Nevertheless, there are examples from amphibians<sup>15</sup> (**Fig. 1A**), reptiles<sup>16</sup>(**Fig. 1B**),  
79 birds<sup>17</sup> (**Fig. 1C**) and wild mammals<sup>18,19</sup> (**Fig. 1D**). There has also been focus on  
80 economically important livestock<sup>8</sup> (**Fig. 1E**; **Supplementary Table1**). Even human  
81 sperm quality is declining, some of which is epidemiologically linked to temperature  
82 variability<sup>10</sup> (**Fig. 1F**). Conservation and captive breeding programs may also be at  
83 risk when animals are kept outside at ambient temperatures due to the negative

84 thermal effects on fertility and fecundity<sup>20</sup>. Warming can affect pollinators by reducing  
85 sperm viability<sup>21</sup>, which is compounded by mated queens storing sperm for months  
86 or years<sup>9</sup>. Conversely, heat suppression of fertility and fecundity in pests or disease  
87 vectors may offer economic benefits<sup>22</sup>.

88

89 However, responses are heterogenous (**Fig.1**) – temperature-induced changes in  
90 fecundity and fertility may be positive, negative or absent depending on a variety of  
91 factors such as species, sex, and life stage and type of thermal exposure(e.g.  
92 constant, fluctuating, extreme). For example, in the mussel, *Mytilus galloprovincialis*,  
93 warmer temperature increases fertilization rate<sup>23</sup> whereas the opposite occurs in the  
94 clam, *Tridacna maxima*<sup>24</sup>. Both sexes may be negatively impacted (**Fig. 1C**), or one  
95 sex may be more susceptible. Effects on fecundity may result from complex  
96 interactions with species-specific ecological traits (**Fig. 1D**) or life history traits, such  
97 as body size<sup>16</sup> but see<sup>25,26</sup>. Higher winter temperatures can also impact spring  
98 fecundity, such as in the wood frog, *Rana sylvatica*<sup>15</sup> (**Fig. 1A**). Predicting whether  
99 fertility and fecundity *per se* is negatively impacted, and for which species under  
100 what thermal conditions, remains challenging, especially given different approaches  
101 to measure the impacts of heat stress (**Box 1**)<sup>7,27,28</sup>.

102

### 103 **Mechanisms of heat-induced fertility loss**

104 High temperature stress damages fertility and fecundity through diverse  
105 physiological and molecular pathways, including impacts on: gamete quantity and  
106 quality; reproductive fluids; sperm storage; rate of fertilisation; the conserved heat  
107 shock response; and gene expression (**Fig. 2; Supplementary Table 1**).

108 Reproductive impairment can occur in both sexes and can have transgenerational  
109 effects. Understanding these mechanisms is vitally important for predicting fertility  
110 resilience, conservation, human health, and protection of agriculture, along with the  
111 potential for fertility recovery, in the face of global warming.

112

### 113 **Gamete effects**

114 Elevated temperatures can impair gametogenesis in both sexes, resulting in reduced  
115 gamete quantity (**Fig. 2; Supplementary Table 1**). For example, heat stress can  
116 result in smaller testes or ovaries<sup>29-31</sup>, increased apoptosis of developing gametes<sup>32-  
117 36</sup> and impaired gamete maturation<sup>29,35,37</sup> resulting in reduced gamete  
118 production<sup>30,32,38-40</sup>. Mature gametes can also have impaired function (**Fig. 2;  
119 Supplementary Table 1**). For example, heat stress can result in sperm that swim  
120 slower<sup>38-40</sup>, have reduced viability<sup>29,40-42</sup>, and sperm and eggs that exhibit more DNA  
121 damage<sup>34,37,43</sup>. In some species, brief heat shock causes immediate and long-lasting  
122 male sterility, consistent with irreparable damage to spermatogenesis  
123 (**Supplementary Table 1**). In other species, males remain fertile initially but become  
124 sterile days later<sup>5</sup>. The causes of this variation are unclear but, in species with  
125 delayed sterility, one possibility is that immature sperm are more heat-sensitive than  
126 mature sperm. As existing mature sperm are depleted, they are gradually replaced  
127 with by sperm that were developing during the heat stress, leading to a delayed  
128 onset of sterility<sup>5,44,45</sup>(**Supplementary Table 1**).

129

130 Heat stress can induce oxidative stress through disruption of mitochondrial function,  
131 generating Reactive Oxygen Species (ROS). Increase in ROS in ovaries and testes  
132 after heat stress causes DNA damage and triggers apoptosis and autophagy  
133 pathways that decrease gamete quantity and quality<sup>39,46</sup>. In *D. melanogaster*

134 laboratory lines, fertility sensitivity to heat stress was correlated with oxidative stress  
135 effects on lifespan<sup>47</sup>, and these patterns were mirrored at the genetic level, where  
136 susceptibility to heat-induced male sterility was associated with genes involved in  
137 DNA damage repair and autophagy<sup>48</sup>. Similarly, DNA damage was linked to heat  
138 stress effects on spermatogenesis in *Caenorhabditis elegans*, but notably not  
139 oogenesis<sup>43</sup>. ROS and heat stress can also impact transposable element activity<sup>43,49</sup>,  
140 which affects sex-specific gene regulation, and can generate novel genetic and  
141 phenotypic variation<sup>50</sup>. In *D. subobscura*, heat stress resulted in different  
142 transposable element expression patterns between the testes and ovaries<sup>51</sup> although  
143 whether this difference is associated with reduced fertility and DNA damage is  
144 unknown. Links between ROS and sex-specific transposable element responses to  
145 heat stress should be assessed for their contribution to taxonomic variation in sex-  
146 specific heat-induced declines of reproductive output.

147

### 148 **Reproductive fluid effects**

149 As well as gametes, both sexes produce reproductive fluid that impact fertilisation  
150 and can mediate how heat stress affects reproductive output. For example,  
151 ejaculates contain seminal proteins which have roles in sperm motility, storage and  
152 female post-mating responses such as increasing egg-laying<sup>52</sup>. In *D. melanogaster*,  
153 heat stress during development reduced the size of the adult male accessory glands  
154 that produce seminal fluid and decreased males' ability to prevent female remating,  
155 suggesting damage to the amount or quality of seminal proteins<sup>41</sup>. In the  
156 lizard, *Tropidurus spinulosus*, female ovarian fluid mitigated negative temperature  
157 effects on sperm velocity, a trait mediating male fertilisation success<sup>53</sup>. In the fish,  
158 *Symphodus ocellatus*, warmer water decreases the extent to which ovarian fluid  
159 biases fertilisation towards high-performing sperm<sup>54</sup>. Thus, the potentially buffering  
160 roles of sex-specific reproductive fluid to high temperature may vary among taxa.

161

### 162 **Sperm storage and fertilisation failure**

163 In species that store sperm, heat stress may substantially reduce stored sperm  
164 viability<sup>40,55</sup>. Whether this reduction arises from the female's inability to maintain  
165 sperm viability under heat stress, or from sensitivity of mature sperm to thermal  
166 conditions during storage, is unknown. In *D. virilis*, female fertility is recovered  
167 following remating after heat stress, suggesting damage to previously stored sperm  
168 rather than to the female reproductive tract<sup>55</sup>.

169 Even if sperm and eggs meet, heat stress can decrease fertilisation success<sup>23,24</sup>  
170 (**Fig. 2; Supplementary Table 1**). In *D. melanogaster*, developmentally heat-  
171 stressed males fertilised fewer eggs and, when fertilisation occurred, embryos were  
172 at an earlier stage of development compared to eggs fertilised by non-heat stressed  
173 males<sup>56</sup>. In mammals, *in vitro* heat stress increases sperm-egg fusion failure<sup>57</sup> and  
174 increases lethal **polyspermy**<sup>58</sup>. Increases in polyspermy were associated with  
175 decreased transcript abundance of a gene involved in preventing polyspermy<sup>58</sup>.

### 176 **Conserved heat shock response**

177 A central defence against thermal stress is the heat shock response, an  
178 evolutionarily conserved cellular programme that includes changes in gene  
179 expression of **Heat Shock Proteins** (Hsps), immune genes and other stress  
180 response pathways<sup>59</sup>. Hsps are essential for gametogenesis<sup>60</sup>. Transcriptome  
181 analysis of testes of pigs<sup>61</sup>, mice<sup>31</sup>, rats<sup>36</sup>, rabbits<sup>62</sup>, chickens<sup>63</sup> and octopus<sup>64</sup> and  
182 ovaries in rabbits<sup>65</sup> and *Drosophila*<sup>51</sup> reveal temperature-driven changes in

183 expression of Hsps and genes associated with oxidative stress, DNA damage repair,  
184 apoptosis, and immunity, and small and micro RNAs (**Fig. 2; Supplementary Table**  
185 **1**). Whether there is sex-specific variation in the strength of transcriptional responses  
186 that underlies sex differences in heat-induced declines of reproductive output<sup>40,48</sup> is  
187 unknown. Male *D. subobscura* exhibited greater Hsp gene expression changes after  
188 acute heat exposure than females, which were associated with increased  
189 transposable element expression patterns between the testes and ovaries although  
190 this was not directly linked to effects on fertility<sup>51</sup>. Mechanistically, Hsp70 drives  
191 transposable element activation in gonads under heat stress in *D. melanogaster*<sup>49</sup>.  
192 Hsps in females from monogamous species or those that store sperm for long  
193 periods, such as in honeybees, may protect stored sperm. For example, honeybee  
194 females increase expression of Hsps in their spermathecae after heat shock<sup>9</sup>.  
195 Likewise, anti-oxidative responses in females could be expected to protect stored  
196 sperm from heat stress. However, no increase in enzymes functioning in anti-  
197 oxidative stress or in GAPDH, which helps maintain stored sperm, was found in  
198 heat-shocked honeybee females<sup>9</sup>. Whether regulation of Hsps relates to species  
199 differences in thermal responses for fertility and fecundity is unknown, though peak  
200 Hsp induction has been linked to differences in CT<sub>max</sub> between populations of  
201 killifish<sup>66</sup> and *Drosophila* species<sup>67</sup>.

202

203 The kinetics of the heat shock response can vary with exposure duration. In female  
204 mice, chronic heat exposure resulted in substantial damage to ovarian function and  
205 elicited sustained Hsp expression changes even after six weeks in benign  
206 conditions<sup>68</sup>. In contrast, acute exposure elicited transient Hsp responses that  
207 returned to baseline within hours with reduced ovarian damage<sup>68</sup>. However, the link  
208 between the gene expression kinetics and reproductive damage is untested.  
209 Generally, upregulation of heat shock responses for an extended period is likely to  
210 be costly<sup>69</sup>, and potentially suggestive of poor adaptation to the thermal  
211 environment<sup>70</sup>. Exposure regime may also alter Hsp expression. In killifish  
212 (*Austrofundulus limnaeus*) liver tissue, small Hsps altered gene expression more  
213 strongly to fluctuating temperatures, while larger chaperones like Hsp70 and Hsp90  
214 were more active under chronic heat<sup>71</sup>. Whether reproductive tissue shows a similar  
215 pattern and how this affects reproductive output was not assessed.

216

### 217 **Epigenetic effects**

218 The heat-induced changes in gonad gene expression discussed above may be  
219 caused by heat stress causing various types of epigenetic modifications (e.g., DNA  
220 or chromatin methylation or acetylation). Epigenetic modifications alter gene  
221 expression, generate phenotypic plasticity and influence phenotypes across  
222 generations<sup>30,50</sup>. In the European corn borer moth (*Ostrinia nubilalis*), heat stress  
223 during pupal and adult life stages increased DNA methylation, with higher rates in  
224 females. In both sexes, genes with methylation shifts were associated with sex-  
225 specific gametogenesis, although heat-stress effects on fertility and fecundity were  
226 not examined<sup>72</sup>. Negative transgenerational effects, in which heat-exposed males  
227 sire offspring with reduced fertility, occur in the red flour beetle *Tribolium castaneum*  
228<sup>40</sup> and the bean weevil *Callosobruchus maculatus*<sup>44</sup> but not in *D. melanogaster*<sup>73</sup>. In  
229 cows, heat stress in the F<sub>0</sub> generation leads to a reduced conception rate in F<sub>1</sub>  
230 daughters and increased stillbirths in F<sub>3</sub> great-granddaughters<sup>74</sup>. What epigenetic  
231 mechanisms caused these transgenerational effects and why taxa vary in responses  
232 is undetermined.

233

### 234 **Fertility recovery after heat stress**

235 The extent and timing of fertility recovery following heat stress dictates the duration  
236 of an individual's absence from the mating pool, which influences other aspects of  
237 fitness and population dynamics, such as sexual selection (**Box 2**). Partial or  
238 complete recovery following heat stress can occur in some species under some  
239 conditions<sup>41,75-77</sup> (**Supplementary Table 1**). In the insect pest, *Monochamus*  
240 *alternatus*, 15d heat stressed individuals showed full recovery of fecundity, sperm  
241 number and sperm viability within four weeks, although recovery time varied across  
242 traits<sup>78</sup>. Recovery was mediated in part by Hsp20, which appeared to help refold  
243 reproductive proteins during the recovery phase, suggesting that Hsps may also  
244 influence longer term recovery after heat stress (see subsection "*Conserved heat*  
245 *shock response*").

246

247 Recovery potential may depend on the severity and duration of heat stress, the  
248 mechanism behind sterility, and the exposed life stage. For instance, adult exposure  
249 duration influenced recovery rates in female *D. melanogaster*, although fertility was  
250 never restored to control levels<sup>32</sup>. In this same species, the extent of recovery was  
251 reduced as temperatures increased, but only when heat stress was applied to the  
252 adult, not pupal, stage<sup>29</sup>. Uncovering the interplay between the extent of reproductive  
253 damage, protective responses, and variation in sex and life history stages that  
254 mediate recovery potential will be key for better predicting how thermal variability  
255 impacts reproductive output and subsequently influences population persistence.

256

### 257 **Variation in thermal vulnerability**

258 Consequences of thermal stress on reproductive output vary, both within and  
259 between taxa, with individuals of some populations or some species being more  
260 resistant than others (see section "Patterns of heat-induced sterility"). Identifying  
261 patterns in factors influencing this variation can help predict which organisms may be  
262 more at risk. Here we examine four factors that mediate thermal stress impacts on  
263 fertility and fecundity – sex-specific effects and its downstream consequences on  
264 sexual selection (**Box 2**), fertilisation mode, life history stage exposed, and exposure  
265 regime. We also consider how different types of phenotypic plasticity influence  
266 variation in reproductive output responses across these factors.

267

### 268 **Sex-specific effects**

269 A key outstanding question is whether fertility and fecundity is more sensitive to  
270 warming in males or females<sup>79</sup> and what the ultimate effect of this sex-specific  
271 variation is on evolutionary responses and population persistence. Female fertility  
272 loss is expected to be more detrimental to population fitness given that females  
273 generally have a lower potential reproductive rate than males<sup>80</sup>. However, most  
274 research has exposed either only one sex or both sexes simultaneously to heat  
275 stress, with the latter typically not delineating sex-specific effects as heat-stressed  
276 individuals are not mated to control mates<sup>14</sup>. This reduces the ability to adequately  
277 assess sex-specific contributions to heat-induced fertility loss. Male fertility is thought  
278 to be more sensitive to high temperature stress due to sperm being particularly heat  
279 sensitive<sup>5,6,29,47,81</sup> (see section "Mechanisms of heat-induced fertility loss"). However,  
280 a meta-analysis spanning 241 aquatic invertebrates and ectothermic vertebrates  
281 found that the sexes are responding similarly for temperature effects on fecundity  
282 and gamete traits<sup>82</sup>. In terrestrial organisms, sex differences for the impact of thermal

283 stress on fecundity appear variable<sup>83</sup>, being more negative for males<sup>29,40,47,84</sup> or  
284 females<sup>17,85-87</sup>, or show no sex difference<sup>22,88</sup>. Determining the extent of sex-specific  
285 variation and what factors contribute to this variation is crucial given the impact on  
286 **operational sex ratio** (OSR), population growth and subsequent ecological and  
287 evolutionary consequences (e.g., **Box 2**; see section “Ecological and Evolutionary  
288 Impacts”).

289

### 290 **Fertilisation mode**

291 The mode of fertilisation alters the environment experienced by gametes, which  
292 could influence the impact of heat stress on fertility and fecundity. External fertilisers  
293 release gametes into the environment, directly exposing them to the abiotic  
294 environment, whereas this is avoided in internal fertilisers. Additionally, the sperm of  
295 internal fertilizers may be stored inside the female, raising the possibility that the  
296 female reproductive tract could protect sperm from heat stress, though this does not  
297 appear to be the case in some insects<sup>9,55</sup>. A recent meta-analysis examining effects  
298 of temperature (but not necessarily heat stress) on fertility and fecundity in aquatic  
299 external and internal fertilising invertebrates and ectothermic vertebrates found weak  
300 support for fertilisation mode moderating thermal fertility effects<sup>82</sup>. Whether stronger  
301 effects would be found when only using studies that applied thermal stress, or  
302 comparing fertilisation mode effects for terrestrial ectotherms that may experience  
303 greater thermal variation compared to aquatic ectotherms, is untested.

304

### 305 **Life stage**

306 Thermal performance curves (**Box 1**) vary across life cycle stages<sup>89</sup>. This  
307 ontogenetic variation can generate demographic bottlenecks, in which a vulnerable  
308 stage may constrain population growth, leading to overestimates of population  
309 resilience when only more tolerant life stages are tested<sup>90</sup>. In two insect species,  
310 heat stress during pupal and adult stages reduced subsequent offspring production  
311 more than exposure during earlier developmental stages<sup>29,45,75,91</sup>. In externally  
312 fertilizing fish, spawners are more heat sensitive, with lower **Thermal Safety**  
313 **Margins** (TSMs) than non-reproductives and juveniles<sup>90</sup>. The meta-analysis across  
314 aquatic invertebrates and ectothermic vertebrates found that the gamete stage was  
315 more thermally susceptible than when developing or adult individuals were  
316 exposed<sup>82</sup>. In contrast, the gamete stage in other taxa is more robust to thermal  
317 stress than later stages<sup>23,92,93</sup>. Determining the relative impact of thermal stress  
318 across the life cycle and why this varies across taxa will improve predictability of  
319 where and when demographic bottlenecks due to heat induced loss of fertility and  
320 fecundity can occur and effects on other evolutionary and ecological processes (e.g.  
321 **Box 2**)– key information relevant for conservation.

322

### 323 **Exposure – duration, frequency and type**

324 Quantifying the consequences of heat stress on trait performance can be done in  
325 different ways that vary the magnitude, duration and frequency of increased  
326 temperature (**Box 1**). Laboratory experiments apply heat stress through acute heat  
327 shock (either static or ramping), prolonged warming under constant or fluctuating  
328 temperatures (with various amplitudes and temporal patterns), or discrete heatwaves  
329 lasting a few days, each potentially producing distinct reproductive outcomes. For  
330 example, across laboratory lines of a *D. melanogaster* population, some lines  
331 maintained fertility when experiencing constant mean high temperature throughout  
332 development but fluctuating temperatures with the same mean reduced fertility in all

333 lines<sup>94</sup>. A meta-analysis across 241 species of aquatic invertebrates and ectothermic  
334 vertebrates found that experimental increases in temperature had more negative  
335 effects on reproductive traits than natural thermal exposure, but exposure duration,  
336 magnitude of temperature increase, and whether temperature treatment was  
337 constant or fluctuating had no effect<sup>82</sup>. Ørsted and colleagues<sup>85</sup> used the Thermal  
338 Death Time approach (**Box 1**) to examine effects on both survival and reproductive  
339 output in *D. sukikii*. Both traits decreased exponentially with increasing temperature,  
340 but reproduction was more sensitive than survival. Using estimated **microclimate**  
341 temperatures from the population's sampling location, models found that damage to  
342 reproductive output accumulated faster than for survival, generating more days in  
343 which high temperature would impair fecundity relative to survival.

344

### 345 **Multiple stressors**

346 While studies show thermal effects on reproductive output loss (**Supplementary**  
347 **Table 1**), climate change also modifies other abiotic factors like UV radiation (which  
348 may increase mutation rates), precipitation, salinity, pH, and seasonal patterns.  
349 Thus, individuals in the wild are typically exposed to multiple stressors  
350 simultaneously. Studies manipulating multiple stressors, such as diet<sup>95,96</sup>, humidity<sup>97</sup>,  
351 pollutants<sup>98</sup> and salinity<sup>23</sup> have shown stressor interactions influence fertility and  
352 fecundity. For example, studies examining the effects of climate change on marine  
353 organisms often test the impact of both rising temperature and ocean acidification  
354 caused by higher dissolved CO<sub>2</sub> levels<sup>99</sup>. The combined effect of these two stressors  
355 can be complex, having negative synergistic effects on fertilisation success in  
356 oysters<sup>100</sup> and sperm swimming speed in mussels<sup>23</sup> whereas in the subarctic  
357 copepod, increasing acidification partly ameliorates the harmful effects of warming  
358 on fecundity<sup>101</sup>. Expanding studies that combine heat stress with other stressors is  
359 important for better increased understanding of climate change impacts on  
360 reproductive output.

361

### 362 **Phenotypic plasticity**

363 Phenotypic plasticity can modulate the effects of heat stress on fertility and fecundity.  
364 We focus on three types of plasticity that have been studied in this context. First,  
365 prior exposure of adults to sub-lethal temperatures can induce reversible  
366 physiological changes (**hardening** or **acclimation**) that improves tolerance to  
367 subsequent extreme temperatures<sup>102</sup>. This can mitigate fertility loss in some species  
368 (e.g. *Drosophila*<sup>69</sup> but see<sup>77</sup>; sea urchins<sup>103</sup>). Second, heat exposure during  
369 development often impairs adult reproduction even when adults experience benign  
370 conditions<sup>48,75,88,104</sup> though such exposure sometimes enhances adult thermal  
371 tolerance<sup>105,106</sup>. Overall, however, most evidence indicates lasting negative  
372 consequences, with a meta-analysis finding no sex difference in acclimation  
373 capacity<sup>107</sup>. Third, parents exposed to heat can alter offspring phenotype via non-  
374 genetic mechanisms, a form of transgenerational plasticity that may be adaptive  
375 when environmental conditions persist across generations<sup>108</sup> (see section,  
376 "Mechanisms of heat-induced fertility loss"). Such plasticity improves offspring  
377 thermal resilience in some species<sup>109,110</sup> but reduces offspring reproductive output  
378 even when offspring develop under benign temperatures in other species<sup>30,40</sup>.  
379 Understanding the evolutionary impact of phenotypic plasticity on heat-induced loss  
380 of reproductive output requires additional research.

### 381 **Ecological and evolutionary impacts**

382 While thermal effects on fertility and fecundity are increasingly well-documented, the  
383 broader ecological and evolutionary impacts remain underappreciated. Here we  
384 explore how heat-induced reductions in fertility and fecundity can shape species  
385 distributions, extinction risk, sexual selection (**Box 2**) and how range shifts due to  
386 suppressed fertility and fecundity from heat stress may impact evolutionary and  
387 ecological responses.

388

### 389 **Species distributions**

390 Understanding how climate change will affect where species can live is a crucially  
391 important research question. Species distribution models (SDMs) predict where  
392 species currently live and incorporate thermal tolerance data in different ways:  
393 mechanistic SDMs use physiological limits directly, statistical or envelope SDMs  
394 infer limits from matching species' occurrence data with climate variables that are  
395 assumed to correlate with physiological limits, and hybrid models that combine the  
396 two<sup>11</sup>. This information can then be used to map areas of predicted suitable habitat  
397 for future climate change scenarios.

398

399 Whether fertility and fecundity limits (TFLs; **Box 1, Fig. 3**) are better predictors of  
400 current species distributions than survival limits (either lethal temperatures or  
401 CT<sub>max</sub>; **Box 1, Fig. 3**), thereby providing better resolved data for forecasting climate  
402 change responses, has been tested in two separate studies, both using multiple  
403 *Drosophila* species<sup>5,6</sup>. Parratt and colleagues<sup>5</sup> compared TFL<sub>80</sub> (the temperature  
404 rendering 80% of the population sterile after a 4-hour static heat shock) with  
405 LT<sub>80</sub>(static 4-hour heat shock) and CT<sub>max</sub> (ramping temperature). Across 43 species,  
406 over 25% had TFLs lower than survival limits the day after heat shock, rising to 44%  
407 seven days later (**Fig. 3A**). The temperature causing 80% of males to be sterile vs  
408 80% to die was species-specific, spanning from 0°C to 4.3°C, changing the species  
409 rank of thermal tolerance and producing narrower estimates of each species' TSM  
410 (**Fig. 3B**). Despite being measured under laboratory conditions, TFL<sub>80</sub> values  
411 improved predictions of current species distributions by over 35% compared to using  
412 CT<sub>max</sub>, indicating the ecological relevance of this trait. This improvement occurred  
413 even when using TFL<sub>50</sub> (**Box 1**), a result confirmed in study by van Heerwaarden and  
414 Sgrò<sup>6</sup>, which used chronic and lower temperature conditions. These findings indicate  
415 many species live closer to a reproductive threshold than previously appreciated,  
416 making some species even more vulnerable to climate change than when  
417 considering survival data alone. While TFL<sub>80</sub>, CT<sub>max</sub> and LT<sub>80</sub> were positively  
418 correlated across species, there was a weaker association between fertility and  
419 survival limits, suggesting distinct underlying processes. However, a TDT study on *D.*  
420 *suzukii* found that fertility and survival limits were strongly correlated, even though  
421 fertility failed at lower temperatures<sup>85</sup>. Together, both TFL and TDT approaches show  
422 reproduction tends to be more thermally sensitive than survival in many species,  
423 although the mechanistic basis for this divergence between reproduction and  
424 survival, and why some species show more of a thermal gap between these two  
425 measurements, is unresolved.

426

### 427 **Population persistence and extinction**

428 Heat-mediated decreases in reproductive output suggests negative consequences  
429 for population persistence, assuming evolutionary potential is limited (see section  
430 "Evolutionary Potential and Constraint"). Whether TFLs predict population extinction  
431 risk has only been directly tested in *Drosophila*<sup>6</sup>. Experimental evolution of six

432 *Drosophila* species under gradual warming (0.2°C every two weeks) found that all  
433 species went extinct within 46 weeks, with tropical species going extinct sooner and  
434 thus at cooler temperatures than temperate species. Male TFLs best explained  
435 extinction probability compared to female TFLs, lethal temperatures, or CT<sub>max</sub> (**Fig.**  
436 **3C**), demonstrating that heat-induced sterility can drive rapid population collapse  
437 with little scope for short-term adaptive responses. In *D. melanogaster*, extinction  
438 occurred at 29.2°C<sup>6</sup> consistent with independent evidence that constant or fluctuating  
439 regimes at this developmental exposure severely reduces both male fertility and  
440 fecundity with low heritability for resistance<sup>94</sup>. Yet other *D. melanogaster* populations  
441 persist in regions that regularly exceed 29°C<sup>112</sup> suggesting **local adaptation** via  
442 mechanisms that mitigate heat damage to reproductive output<sup>76</sup> (see section  
443 “Evolutionary Potential and Constraint”).  
444

445 Further insight comes from the sterile insect technique (SIT), in which mass release  
446 of sterile males, either through ionizing radiation or, more recently, through genetic  
447 manipulation, is used to suppress pest populations<sup>113</sup>. Population crashes can be  
448 rapid, with guidelines suggesting release of between 90 and 99% sterile males<sup>113</sup>.  
449 Although natural heat extremes are currently unlikely to cause sterility on this scale,  
450 population declines do not need to be immediate to have ecological consequences.  
451 At least two factors are expected to influence the proportion of infertile males needed  
452 to reduce the population growth rate, and by extension, the vulnerability of  
453 populations to warming-induced infertility. One is related to mating behaviour and  
454 sexual selection (**Box 2**). If sterile males are less competitive – for instance, through  
455 reduced mating success, production of fewer sperm, or reduced ability to suppress  
456 female remating – this could reduce the demographic cost of male sterility<sup>114</sup>.  
457 Moreover, as SIT eliminates reproduction for most males, this will produce extreme  
458 variance in male reproductive success, which could select for increased female  
459 discrimination against sterile males<sup>115</sup> (**Box 2**). Whether this evolutionary response  
460 could emerge under natural heat-induced male sterility is unexplored. The second  
461 factor is fertility recovery after heat stress<sup>114</sup> (see the Mechanisms subsection,  
462 “Fertility recovery after heat stress”). Demography will be negatively impacted when  
463 sterility is long-lasting relative to the organism’s life span or irreversible.  
464

### 465 ***Sympatric species and adaptive introgression***

466 Species are shifting polewards in response to rising temperature<sup>116</sup> potentially  
467 bringing closely related species into secondary contact. If reproductive isolation  
468 barriers are incomplete, then such shifts into sympatry may result in increased gene  
469 flow and recombination arising from hybridization between taxa<sup>117</sup>. Hybridisation  
470 could have either negative, positive or a mix of fitness consequences.  
471

472 Negative hybridization consequences can occur when increased sympatry generates  
473 **reproductive interference**<sup>118</sup>, which could be exacerbated under climate change if  
474 these species differ in thermal fertility sensitivity. For example, if females of a more  
475 thermally resilient species mate with males from a more sensitive species, who may  
476 be sterile, this could negatively impact female reproductive success. On the island of  
477 São Tomé, two sister species, *D. santomea* and *D. yakuba*, exhibit different thermal  
478 fertility sensitivities and meet in a contact zone, generating some hybrids<sup>119</sup>. Because  
479 matings between *D. yakuba* females and the more thermally sensitive *D. santomea*  
480 males are more likely than the reciprocal<sup>120</sup>, high temperatures could exacerbate  
481 reproductive interference by generating more (costly) hybrids. Increased

482 hybridization could either result in reduced species barriers or select for  
483 **reinforcement** of stronger prezygotic barriers<sup>121</sup>. Experimental evolution with these  
484 two species showed reinforcement of prezygotic gamete barriers that reduced  
485 hybridization cost<sup>122</sup>, but temperature was not used to change hybridization costs,  
486 leaving the role of differential thermal fertility between sympatric species an open  
487 question. In the marine tubeworm, *Galeolaria*, reproductive isolation is strong at  
488 cooler temperatures between two sympatric species but higher temperatures  
489 increase cross-fertilisation success<sup>123</sup>. Whether this hybridization is costly or  
490 beneficial is unknown.

491  
492 Hybridization may be beneficial by allowing acquisition of thermal fertility resilience  
493 alleles from a more warm-adapted species. Such **adaptive introgression** may  
494 provide a route for rapid evolutionary change, although this could also blur species  
495 boundaries<sup>124</sup>. For example, in the copepod *Tigriopus californicus*, experimental  
496 hybridization of two populations with divergent heat tolerance followed by  
497 resequencing found increased survival heat tolerance in hybrid lines associated with  
498 introgression from the more heat-tolerant southern population<sup>125</sup>. Fertility effects  
499 were not tested.

500

### 501 ***Invasive species***

502 Invasive species have multiple ecological and evolutionary consequences on  
503 communities and ecosystems<sup>126</sup>. They harm native species through ecological  
504 competition and can exhibit superior thermal performance and phenotypic  
505 plasticity<sup>127</sup>. Despite this, no direct comparison of thermal sensitivity in fertility either  
506 between invasive and native species or between native and invasive populations of  
507 the same species have been assessed. However, in the round goby, an invasive  
508 species that has adapted to local salinity by improving sperm velocity has enabled  
509 population spread<sup>128</sup>. This highlights both the potential for local adaptation and the  
510 threat of invasive species and focuses knowledge acquisition on understanding the  
511 extent of genetic variation within and between populations and species in thermal  
512 responses of factors influencing reproductive output.

513

### 514 **Evolutionary potential and constraint**

515 Thermal fertility limits place an upper bound on the ability of populations to  
516 reproduce under climate warming. Niche tracking to higher altitudes or latitudes may  
517 buy time, but is limited by geography. Sustained persistence requires *in situ* adaptive  
518 evolution of greater heat tolerance for fertility and fecundity. Below, we synthesize  
519 factors influencing the evolution of fertility tolerance, including heritability and genetic  
520 architecture, mutational input and epigenetic change, and geographic variation and  
521 local adaptation in thermal fertility resilience.

522

### 523 ***Adaptive potential***

524 Evolutionary potential to increase thermal fertility tolerance (e.g. shifting TFLs to the  
525 right; **Box 1, Fig. C**) requires heritable genetic variation in relevant physiological  
526 processes (see section “Mechanisms of heat-induced fertility loss”). Empirical  
527 estimates of this variation are scarce and reflect broad-sense heritability. These are  
528 point estimates of evolutionary potential that do not separate additive genetic  
529 variation from other sources of variation and are subject to several different factors  
530 that affect the heritability estimate (i.e., methodological, life stage, population) that  
531 need to be considered when predicting potential adaptive responses<sup>129</sup>. A study in

532 mice (*Mus musculus*) found genetic variation in fertility of heat-stressed males, with  
533 resistant males being superior in several traits related to offspring production, with  
534 heritability per trait ranging from 0.09-0.13 after heat stress<sup>130</sup>. In *D. melanogaster*,  
535 developmental exposure to chronically high temperatures indicated low heritability  
536 for fertility tolerance, but broad-sense heritability rose as stress increased, revealing  
537 **cryptic genetic variation (CGV)**<sup>94</sup>. The release of CGV is a common response  
538 under genetic or environmental stress, resulting in increased trait variance due to  
539 DNA repair mechanisms losing fidelity, subsequently generating phenotypic plasticity  
540 and extreme phenotypes that could facilitate adaptation to novel environments<sup>131</sup>.

541  
542 Despite there being evidence for CGV in the heat tolerance of reproductive traits,  
543 multi-generational selection experiments in several *Drosophila* species failed to elicit  
544 evolutionary shifts in male fertility limits<sup>6</sup> or female fecundity<sup>132</sup> under steadily  
545 increasing temperatures. The lack of heat tolerance response echoes patterns for  
546 non-fertility traits<sup>133</sup>, in which upper thermal tolerances are typically more constrained  
547 than lower tolerances<sup>134</sup>. However, in *T. castaneum* males undergoing experimental  
548 evolution under constant high temperature were found to have improved fertility  
549 under subsequent heatwave conditions at even higher temperatures<sup>135</sup>, suggesting  
550 that sustained selection can sometimes yield increased fertility tolerance.

551

### 552 **Genetic architecture**

553 The genetic architecture of adaptive traits can also impact evolutionary response.  
554 With sufficient genetic variation, evolution can be facilitated or constrained by  
555 selection on pleiotropically or physically linked traits. Constraints occur when  
556 selection acts non-orthogonally to genetic variance among genetically linked traits,  
557 indicating **antagonistic pleiotropy**<sup>136</sup>. For example, a negative genetic correlation  
558 between heat and cold reproductive tolerance in ostriches (*Struthio camelus*) may  
559 constrain adaptation to increasing fluctuating temperatures<sup>17</sup>. In *C. maculatus*,  
560 experimental lines evolving under climate warming had increased longevity but  
561 reduced reproduction, indicating a trade-off in life history investment<sup>137</sup>. However, in  
562 nearly-isogenic *D. melanogaster* lines, genetic variation associated with thermal  
563 fertility effects was uncorrelated with many other stress responses, including CTLs,  
564 suggesting their independent evolution<sup>47,94</sup>. The typically positive relationship  
565 between body size and fecundity<sup>138</sup> but the negative relationship between high  
566 developmental temperature and body size in ectotherms<sup>102</sup> may impact the ability for  
567 reproductive output to respond to climate warming if genetically correlated. However,  
568 populations can vary in the extent of the relationship between developmental  
569 temperature and body size<sup>139</sup>. Moreover, fecundity under high thermal stress can be  
570 reduced independently of body size<sup>26</sup> and experimental warming studies show  
571 conflicting results on evolution of body size, including its relationship to reproductive  
572 output<sup>140,141</sup>. So whether changes in body size, which has been suggested to  
573 represent a third universal response to climate warming<sup>142</sup>, genetically influences the  
574 evolution of reproductive output as temperatures continue to rise requires substantial  
575 experimental dissection.

576

577 Sex-specific genetic architecture may also impact responses. In ostriches, individual  
578 variation in thermal fecundity resilience was found for both males and females.  
579 However, some females were able to increase both egg number and mass at high  
580 temperatures, without a trade-off with egg mass at other temperatures indicating  
581 adaptive genetic variation in females for that perform well at multiple temperatures<sup>17</sup>.

582 In *C. maculatus*, selection for male sexual competitiveness resulted in increased  
583 **thermal sensitivity of fertility (TSF; Box 1)** in both sexes, suggesting that sexually  
584 selected traits carry hidden costs for fertility under heat stress and that heat  
585 sensitivity of female reproductive output is genetically correlated with sexually  
586 selected reproductive traits in males<sup>44</sup> (**Box 2**). Conversely, *D. melanogaster* lines  
587 revealed a weak correlation between thermal sensitivity of male and female fertility<sup>47</sup>,  
588 suggesting potential for sex-specific evolution in some systems.

589

### 590 **Thermal induction of mutations**

591 While standing genetic variation is critical to rapid evolutionary responses, mutations  
592 are the ultimate source of genetic variation. Environmental stress can trigger  
593 mutagenesis via mechanisms such as increased DNA damage and/or decreased  
594 DNA repair - processes related to compromised fertility under heat stress (see  
595 section "Mechanisms of heat-induced fertility loss"). While most mutations are, on  
596 average, deleterious, higher temperatures can increase mutational variance,  
597 enhancing selection efficiency and accelerating adaptation<sup>143</sup>. Heat stress can trigger  
598 increased transposable element activity that can generate mutations<sup>50</sup>. Additionally,  
599 heat stress may interact with other mutation inducing stressors. For example, in *C.*  
600 *maculatus*, lines evolving under warming had enhanced germline repair after  
601 exposure to mutation-inducing radiation<sup>137</sup>, hinting that selection to warming can  
602 affect mutational robustness. However, whether elevated mutation rates in response  
603 to increasing temperature can provide **evolutionary rescue** to fertility of animal  
604 populations is untested, although there is evidence that increased mutation rate can  
605 result in thermal adaptation in *Escherichia coli*<sup>144</sup>.

606

### 607 **Latitudinal variation of fertility resilience**

608 Tropical and temperate species experience distinct thermal regimes. Tropical  
609 species tend to be adapted to relatively stable and warm temperatures and live  
610 closer to their thermal limits (i.e. have a narrower TSM), such that both increases in  
611 the mean temperature and its variability are predicted to make tropical species  
612 vulnerable to even modest warming<sup>2</sup>. While limited in scope, across six *Drosophila*  
613 species, TFL<sub>50</sub> occurs at lower temperatures in tropical species, indicating lower  
614 fertility resilience and faster extinction compared to temperate species<sup>6</sup>. Generally,  
615 tropical species also exhibit narrower thermal fertility safety margins<sup>6</sup> while having  
616 higher warming tolerance and CT<sub>max</sub>-based thermal safety margins<sup>145</sup>. However,  
617 whether tropical species are more vulnerable to temperature increases induced by  
618 climate change is debated<sup>146</sup>. Analysis of 38 ectotherm species suggested higher  
619 extinction risk in temperate species owing to greater thermal variance and longer  
620 extreme events (i.e., longer periods of heat stress in the summer) compared to  
621 tropical species<sup>147</sup>. Note though that this study could not disentangle temperature  
622 effects on fertility from survival.

623

### 624 **Local adaptation**

625 Thermal tolerance studies often use one population to represent a species, which  
626 may suffice if thermal limits show limited evolutionary potential. However, trait values  
627 can vary across a species' distribution range in response to variation in local  
628 ecology, enabling **local adaptation**. Locally adapted populations by definition  
629 harbour locally beneficial alleles. Local adaptation for fertility tolerance occurs in *D.*  
630 *subobscura*<sup>87,148</sup> and *D. melanogaster*<sup>76</sup>, in which low latitude populations exhibit  
631 higher fertility resilience than higher latitude populations. In the ostrich, females with

632 higher egg laying rates under hotter temperatures regulated their head temperature  
633 better<sup>149</sup>. This response was both heritable and exhibited a signature of local  
634 adaptation since females from more variable and unpredictable areas had greater  
635 thermoregulatory head capacity. Determining whether there is local adaptation of  
636 fertility and fecundity in response to heat stress is important since these alleles could  
637 be transferred to other populations via gene flow. Moreover, incorporating local  
638 adaptation into predictions of how species will respond to climate change can  
639 improve the quality of these forecasts.

640

### 641 **Summary and future perspectives**

642 Reproduction underpins population persistence, yet fertility and fecundity remain  
643 under-represented in forecasts of species' responses to climate warming<sup>3,81</sup>.

644 Reproductive failure can occur at temperatures well below lethal temperatures,  
645 shown across diverse animal taxa. Research has focused on model organisms or  
646 livestock, but heat stress consistently reduces gamete quality, reproductive fluids,  
647 and fertilization success, often via DNA damage and oxidative stress. Hsps and  
648 other stress-related genes seem to play central roles. Male fertility appears more  
649 sensitive to heat stress than female fertility, but sex-specific effects on fecundity are  
650 more variable. External fertilizers may be more vulnerable than internal fertilizers  
651 although data are sparse. Life history stages vary in both heat sensitivity and  
652 potential for recovery, with important implications for population dynamics. Plastic  
653 responses may be limited for buffering fertility.

654

655 Ecological and evolutionary impacts of heat-induced sterility are under-studied and  
656 taxonomically limited. *Drosophila* studies show thermal fertility limits generate more  
657 narrow thermal safety margins, increase extinction risk, and better predict current  
658 species distributions compared to death temperatures. However, similar studies in  
659 other taxa are lacking, the link between fertility loss and range limits remains  
660 correlative, and the impact of other factors such as behavior, acclimation, and the  
661 use of microclimates<sup>111</sup> in buffering fertility impacts is unknown. While there is low  
662 heritability of fertility resilience, little is known about the role of genetic architecture,  
663 mutations, or hybridization in shaping its adaptive potential. This potential is also  
664 contingent on demographic and ecological context with small populations, species  
665 with narrow ranges, and geography (i.e., tropical versus temperate habitats)  
666 impacting vulnerability. These taxa also face other anthropogenic stressors,  
667 reinforcing the need for multi-stressor experiments. Invasive species may prove  
668 more resilient but this requires study. Impacts of heat-induced sterility on sexual  
669 selection remains strikingly under-studied.

670

671 Thus, as a burgeoning field, important knowledge gaps remain. Below we highlight  
672 six research priorities to facilitate knowledge that will provide better predictive  
673 abilities of future fertility and fecundity costs and responses to climate change.

674

675 1. **Expand taxonomic breadth.** Much of the mechanistic and ecological effects  
676 of reproductive output loss in response to warming come from a narrow set of model  
677 and agricultural organisms. Broader phylogenetic sampling is essential to identify  
678 generality and outliers, and to uncover factors causing some taxa to be more  
679 vulnerable. Surveying multiple populations is critical to quantify genetic variation that  
680 could respond to thermal selection for fertility and fecundity resilience.

681 2. **Integrate functional and ecological endpoints.** Understanding what  
682 magnitude and duration of thermal exposure is most relevant for each taxon, and  
683 integrating these data into models of population persistence (e.g. species ranges,  
684 extinction risk) is needed. Modelling efforts are essential to simulate diverse  
685 scenarios predicting male and female responses across life history stages,  
686 identifying conditions that promote population persistence vs those leading to  
687 extinction. Experimental studies could validate these models, deepening  
688 understanding of species-specific vulnerabilities and informing conservation  
689 strategies.

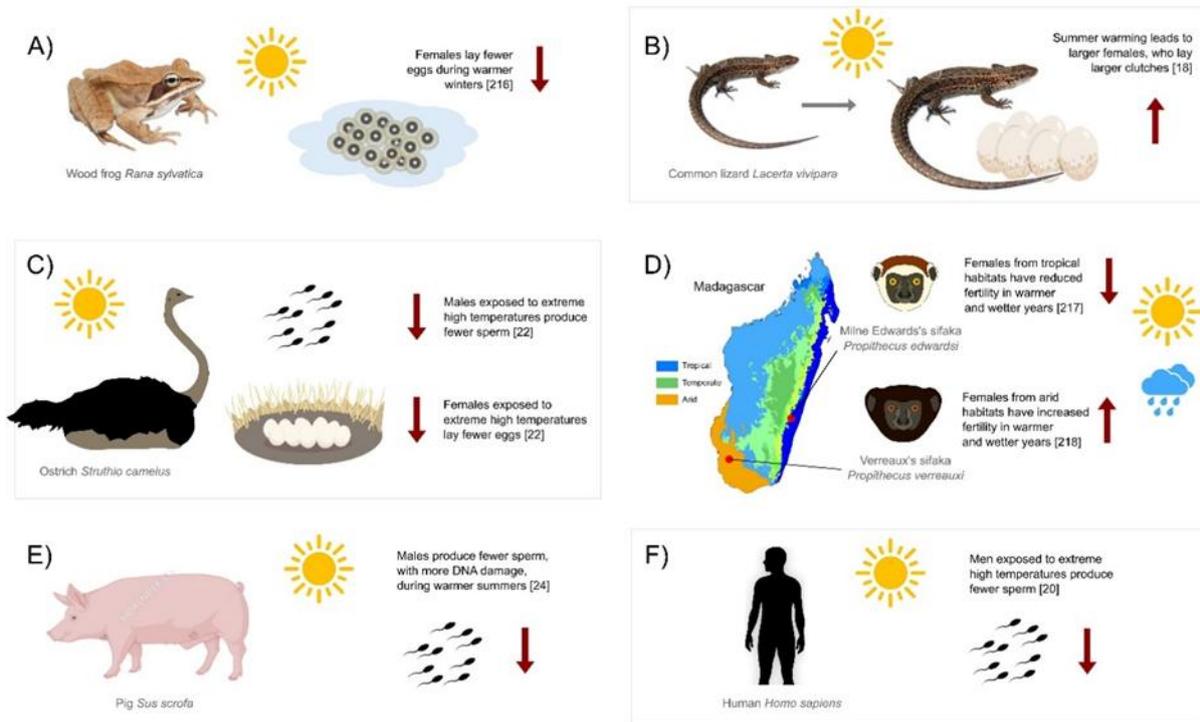

690 3. **Incorporate multi-stressor scenarios.** Interactions between heat and other  
691 stressors could mean that lower temperatures with milder fertility and fecundity  
692 effects (e.g., TFL<sub>30</sub>) generates a larger effective reproductive loss (e.g. TFL<sub>50</sub>) under  
693 the same temperature. Multi-stressor experiments are necessary.

694 4. **Evaluate broader community and ecosystem consequences.** Range shifts  
695 are a common climate change response<sup>116</sup>, and male TFLs may partly underlie  
696 observed patterns. Whether variability in thermal fertility tolerance, including  
697 invasive species and hybridization potential, has community effects is unknown.  
698 Studies assessing species-specific CTmax effects on community interactions have  
699 found range shifts and variability in critical thermal tolerance across trophic levels  
700 alters species composition and community interactions, changes food webs<sup>150</sup>, and  
701 modifies density-dependent competition processes<sup>151</sup>. Similar studies could  
702 illuminate whether species-specific TFLs also have broad community and ecosystem  
703 consequences.

704 5. **Determine interactions with other evolutionary processes and the  
705 impact of genetic architecture.** Both natural selection (e.g. differences across life  
706 history stages in how heat stress impacts trait expression and fitness consequences)  
707 and sexual selection, along with genetic correlations between traits within and  
708 between the sexes, impact evolutionary response. More sophisticated experiments  
709 across taxa quantifying how these factors impact the evolution of reproductive output  
710 tolerance under a warming world are necessary.

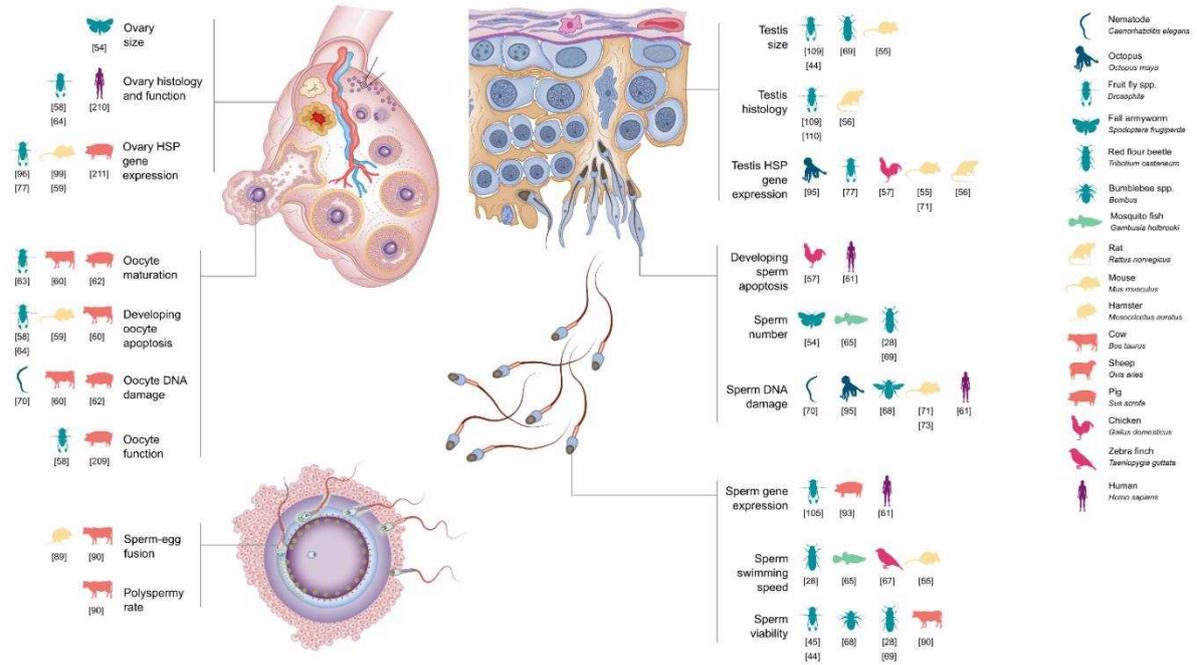

711 6. **Translate mechanistic insights into applied solutions.** Shared pathways of  
712 thermal reproductive damage across species offer targets for conservation,  
713 agriculture and aquaculture interventions. Agricultural practices have incorporated  
714 cooling and selective breeding to prevent fertility loss<sup>152</sup>, but this has not translated  
715 to considerations for wild organisms. However, despite shared pathways, related  
716 taxa clearly vary in thermal fertility resilience, that may be locally adaptive. Genomic  
717 screening for such resilience along with selective breeding or adaptive introgression  
718 could provide management solutions for vulnerable or economically important taxa.

719 In sum, safeguarding biodiversity, and therefore its ecosystem services, in a  
720 warming world requires not only on keeping organisms alive but also keeping them  
721 reproducing. Examining the consequences of warming on reproductive output can  
722 deliver more realistic projections of organismal responses to climate change and  
723 improve design of effective conservation and management interventions. Expanded  
724 research in this area will provide fundamental insights into biodiversity's future under  
725 rapid environmental change.

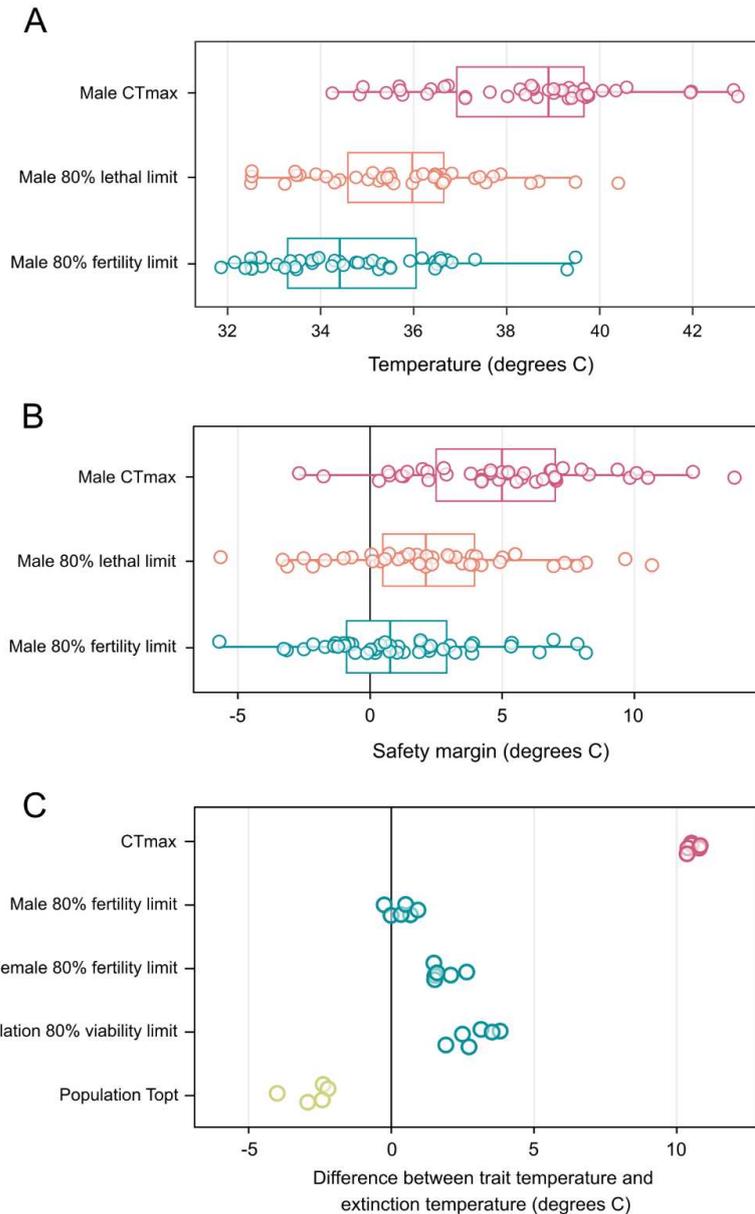

727

**Fig. 1.** Temperature effects on reproductive output are variable and taxonomically widespread. **A)** Warmer winters in the midwestern United States reduce female fecundity in the wood frog, *Rana sylvatica*<sup>15</sup>. **B)** In contrast, female common lizards (*Lacerta vivipara*) from southern France born in warmer years mature at a larger size and so produce larger clutches<sup>16</sup>. **C)** Ostriches (*Struthio camelus*) breeding in South Africa are regularly exposed to large temperature extremes, and extreme high temperatures cause females to lay fewer eggs, and males to transfer fewer sperm during mating<sup>17</sup>. **D)** In Madagascar, the effect of climate on breeding in sifakas differs across species. Female Verreaux’s sifakas (*Propithecus verreauxi*) living in the arid south of the island have higher fertility in warmer and wetter years<sup>18</sup>. In contrast, female Milne Edward’s sifakas (*Propithecus edwardsi*) living in the tropical, mountainous east of the island have reduced fertility in warmer and wetter years<sup>19</sup>. **E)** High temperatures can also impact the fertility of species used in an agricultural setting. For example, domestic boars (*Sus scrofa domestica*) reared in tropical Australia produce fewer sperm with more DNA damage in warmer summers<sup>8</sup>. **F)** High temperatures also impair the fertility of human men. For example, Chinese men exposed to high temperatures 0-90 days before they visited a sperm bank had reduced sperm quality<sup>10</sup>.

**Fig. 2.** Generalised schematic of animal reproduction, identifying the timing and mechanism of heat stress impacts. We focus on processes from gamete formation to fertilisation, including gonad function. Annotations are where evidence exists from studies in **Supplementary Table 1** that processes are abnormal under heat stress compared to benign conditions.

756

757

758 **Fig. 3. The ecological relevance of thermal fertility limits. A)** Across 43 species

759 of *Drosophila* fruit fly, the 80% male Thermal Fertility Limit (TFL; green points) tends

760 to occur at a lower temperature than either the 80% Lethal Limit (LT; orange points)

761 or the Critical Thermal Maximum ( $CT_{max}$ ; red points). **B)** Across 43 species of

762 *Drosophila* fruit fly, the 80% male Thermal Fertility Limit (TFL; green points) has a

763 narrower Thermal Safety Margin than either the 80% Lethal Limit (LT; orange points)

764 or the Critical Thermal Maximum ( $CT_{max}$ ; red points). Data in A) and B) adapted from

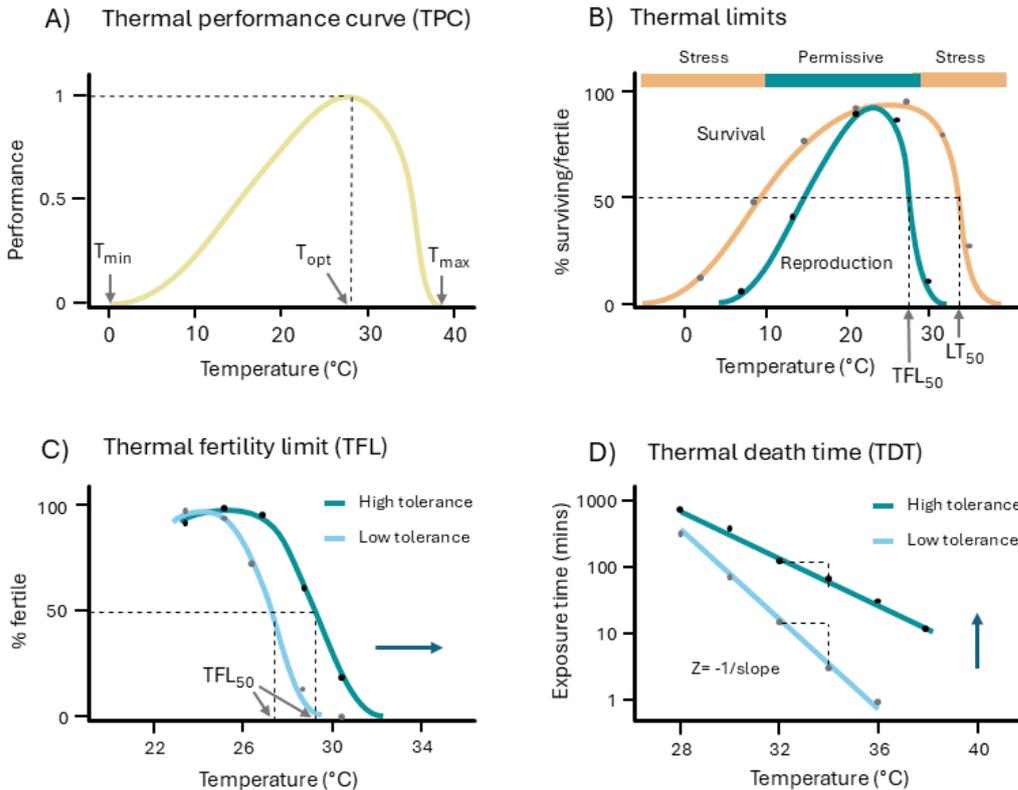

765 <sup>5</sup>. **C)** Across six species of *Drosophila* fruit fly, the temperature at which laboratory

766 populations go extinct is almost identical to the 80% male Thermal Fertility Limit

767 (TFL). The 80% female TFL, or any other metrics of population viability, are less

strongly related to extinction temperature. Data adapted from<sup>6</sup>.

768 **Box 1. Measures of thermal tolerance**

769 Thermal tolerance can be summarized by a **Thermal Performance Curve (TPC)**,  
 770 which plots trait performance across temperatures<sup>153</sup>(**Fig. a**; note, curves in all  
 771 panels are hypothetical). TPCs are typically unimodal and asymmetric, with  
 772 performance declining steeply at higher temperatures<sup>154,155</sup>; **Fig. a**). TPCs describe  
 773 thermal tolerance by determining the temperature that maximizes performance ( $T_{opt}$ ;  
 774 dashed line **Fig. a**), and the lower ( $T_{min}$ ) and upper ( $T_{max}$ ) thermal limits at which  
 775 performance fails (**Fig. a**). Intervening temperatures describe the 'permissive' region  
 776 which allows life-cycle completion, including reproduction and anything outside of  
 777 this region is stressful<sup>4,156</sup>(**Fig. b**). TPCs have been used to predict how organisms  
 778 will respond to climate change<sup>134,145</sup>.

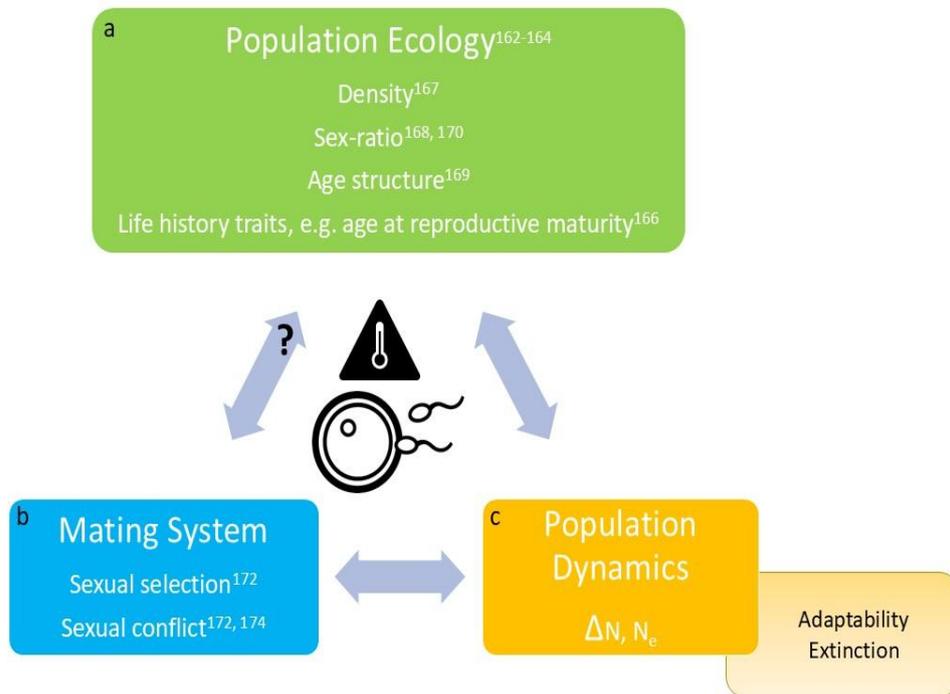

780  
 781 Survival (binary trait) can be measured using **Critical Thermal Limits**, the  
 782 temperature at which individuals lose coordination or motor function(**Critical thermal**  
 783 **maximum [CT<sub>max</sub>]** and **Critical thermal minimum [CT<sub>min</sub>]**), or via **Lethal**  
 784 **Temperatures(LTs)**, the temperature at which individuals die<sup>2</sup>. For example,  $LT_{50}$   
 785 indicates the temperature at which 50% of a cohort dies (**Fig. b**; dashed  $LT_{50}$  line,  
 786 orange curve). These assays usually apply heat acutely, either statically for a set  
 787 time period at a particular temperature or through ramping the temperature at some  
 788 rate until physiological failure occurs.

789  
 790 Similarly, fertility endpoints can be assessed using **Thermal Fertility Limits**<sup>7</sup> (TFLs;  
 791 **Fig. b**), which measures the proportion of individuals that are **sterile/infertile** (e.g.  
 792 50% for  $TFL_{50}$ ; **Fig. b**, dashed  $TFL_{50}$  line, green curve) after heat exposure. A higher  
 793 TFL indicates greater heat tolerance (**Fig. c**, arrow showing shift to right, dark blue  
 794 line). High and low tolerance can represent variation between the sexes,  
 795 populations, species, life history stages, and fertilization mode. Because fertility  
 796 cannot be directly observed, TFL assays use static rather than ramping exposures<sup>7</sup>.

797 Heat stress effects on reproductive output can also be assessed using **Thermal**  
798 **Sensitivity of Fertility (TSF)** in which fecundity (e.g. egg or offspring number) at a  
799 small number of test temperatures is determined<sup>7,83</sup>. The greater the difference  
800 between temperature treatments, the greater the sensitivity. Designs can vary by  
801 using either acute exposure of a few hours (to mimic the hottest part of the day  
802 during a heatwave), or longer exposure across several days (to mimic the full  
803 duration of a heatwave), or chronic exposure across weeks or months (to mimic  
804 long-term changes in climate<sup>7,14</sup>).

805  
806 This variation links to the issue that thermal injury may accrue over time in a dose-  
807 dependent way<sup>27</sup>, which these methods do not test. The **Thermal Death Time**  
808 approach (TDT) explicitly addresses this by integrating exposure time and  
809 temperature with log-transformed exposure duration resulting in some performance  
810 outcome (e.g. 50% loss of fertility) plotted against temperature<sup>4</sup> (**Fig. d**). This  
811 captures how milder stress over longer periods can cause similar damage to acute  
812 extremes. Higher thermal tolerance (**Fig. d**, arrow) is indicated by a shallower  
813 negative slope<sup>4</sup> (**Fig. d**, dark blue line) with sensitivity quantified by  $z$  (**Fig. d**, dashed  
814 lines). TDT studies improve predictions of organismal response to high  
815 temperatures<sup>157,158</sup>. Only one TDT study has assessed fertility, finding that heat-  
816 induced sterility in *D. sukukii* followed a dose-dependent relationship, similar to  
817 survival traits, but occurring at lower temperatures<sup>85</sup>. However, debate remains on  
818 the most ecologically relevant way to measure thermal tolerance, including other  
819 approaches that integrate exposure duration and thermal intensity<sup>28,159</sup>.

820 **Box 2. Sexual selection and heat-induced sterility**

821  
 822 Rising temperatures can influence sexual selection via heat-induced reductions in  
 823 fertility and fecundity. This is important because sexual selection may promote  
 824 adaptation by purging deleterious alleles or hinder it by escalating sexual conflict and  
 825 reducing female fitness<sup>160,161</sup>. Ecological factors are key influencers of mating  
 826 systems<sup>162,163</sup>, shaping both the strength and sex-specific direction of sexual  
 827 selection and sexual conflict and sexually antagonistic coevolution<sup>163,164</sup>. Previous  
 828 reviews have highlighted that the interaction between thermal ecology and sexual  
 829 selection is of major interest<sup>165</sup>, but here we focus on how heat-induced sterility  
 830 sexual selection, an area largely overlooked.

831  
 832 Heat stress reductions in fertility and fecundity (**Fig.**, central image) directly changing  
 833 population size ( $\Delta N$ ) and effective population size ( $N_e$ ), impacting genetic variation  
 834 and evolutionary consequences of these changes (**Fig. c**), while altering ecological  
 835 parameters (**Fig. a**). These population-level parameters influence mating systems<sup>166-</sup>  
 836 <sup>170</sup>, and both sexual selection and sexual conflict (**Fig. b**). All interact to determine  
 837 adaptability and extinction probability, although whether there is a reciprocal effect of  
 838 sexual selection on ecological parameters is uncertain<sup>171</sup> (**Fig. b**, ? going toward **Fig.**  
 839 **a**). Some research has begun to ask how heat-induced sterility impacts these  
 840 ecological components. In *D. virilis*, pupal heat stress delays reproductive maturity,  
 841 leaving many adults temporarily infertile whereas adult stress causes permanent  
 842 sterility<sup>77,166</sup>, which can age-restructure populations. Moreover, if the sexes differ in  
 843 thermal sensitivity, the OSR shifts<sup>166</sup>, modifying sex-specific variance in reproductive  
 844 success and the strength and direction of sexual selection.

845  
 846 Heat-induced sterility may also select for different mating behaviours, impacting  
 847 sexual selection. Mating with sterile males often triggers facultative polyandry as a  
 848 fertility assurance strategy<sup>172</sup>, intensifying sexual conflict and changing sex-specific  
 849 variance in reproductive success. Condition-dependent male signals<sup>173</sup> may be

850 reduced by heat stress, favouring female choice for fertile males<sup>174</sup>. Conversely,  
851 reduced female fecundity may drive male mate choice toward more fecund  
852 partners<sup>174</sup>. These behavioural and OSR-mediated effects alter the strength and sex-  
853 bias of sexual selection. A meta-analysis suggests warming generally reduces  
854 variance in male fitness while increasing variance in females<sup>165</sup>, though data specific  
855 to heat-induced sterility were lacking.

856

857 Sexual selection may change how the sexes invest in reproductive success and heat  
858 stress may reveal trade-offs in this investment. In two insect species, males evolving  
859 under regimes promoting greater sexual selection showed reduced progeny  
860 production<sup>44</sup> or sperm competitiveness<sup>175</sup> after heat stress. This may reflect a trade-  
861 off between investment in intensified male-male competition and germline  
862 maintenance<sup>176</sup>. In contrast, multigenerational experimental sexual selection in other  
863 taxa indicates polyandry can benefit populations: when both sexes experience  
864 warming, populations with a history of strong sexual selection have higher  
865 fecundity<sup>177-179</sup>.

866

867 Overall, heat-induced fertility and fecundity declines has the potential to reshape  
868 interactions between ecology, demography, and sexual selection. However, current  
869 data are limited and taxonomically biased. Expanding research across diverse taxa  
870 and ecological contexts is critical to determine whether altered mating systems in  
871 response to heat-induced sterility buffer populations against climate change or  
872 hasten their decline.

873 **Glossary**

874 **Acclimation** - Physiological adjustment to an increase in temperature, particularly  
875 where longer-term exposure to a mildly stressful temperature can increase the  
876 tolerance of a subsequent higher temperature.

877  
878 **Adaptive introgression** – where genes from outcrossing to other populations or  
879 species improve fitness under novel conditions.

880  
881 **Antagonistic pleiotropy** – when a gene/allele has beneficial effects in one/some  
882 traits but negative effects for other traits.

883  
884 **Critical Thermal Limit** - The upper ( $CT_{max}$ ) or lower ( $CT_{min}$ ) temperature at which  
885 critical biological function (often measured as motor control or coordinated  
886 movement) is lost, or death occurs.

887  
888 **Cryptic Genetic Variation (CGV)** – genetic variation that is normally masked,  
889 having little to no effect on the phenotype, but that is exposed under stressful  
890 conditions, thereby putatively available to fuel adaptation.

891  
892 **Critical Thermal Maximum ( $CT_{max}$ )** - the highest temperature at which a  
893 physiological function is lost (often measured as motor control or coordinated  
894 movement), or death occurs.

895  
896 **Evolutionary rescue** – selection for evolutionary change enabling individuals to  
897 survive under stressful or novel conditions and is sufficiently rapid to save a  
898 population from extinction

899  
900 **Fecundity** - Number of eggs or viable offspring produced by an individual. Note that  
901 in the medical literature the definitions of fertility and fecundity can be switched in  
902 meaning compared to those used in most non-human contexts. When fecundity is  
903 measured as the number of eggs produced, then effects of heat treatment on  
904 offspring survival is not conflated. However, in many taxa, only offspring number is  
905 reported. In cases where a paper reports offspring number, we included it in our  
906 review only when the parents, and not offspring, were placed under heat stress. This  
907 limits the potential confounding effect of heat stress on survival of offspring that is  
908 separate from the parental effect.

909  
910 **Fertility** - Ability to produce viable offspring. Note that in medical literature the  
911 definitions of fertility and fecundity can be switched in meaning compared to those  
912 used in most non-human contexts.

913  
914 **Hardening** – A period of elevated temperature that improves performance under  
915 subsequent higher (extreme) temperatures.

916  
917 **Heatwave (or heat wave)** – A meteorological term for a sustained period of  
918 abnormally warm weather that last for multiple days, measured relative to the normal  
919 climate for a given location and time of year. There is no universally agreed definition  
920 for the duration and severity of a heatwave; as a rough estimate, most definitions  
921 require three to five consecutive days of temperatures 5°C or more above the

922 seasonal average. Many studies attempt to mimic heatwaves to make their  
923 temperature manipulations more ecologically realistic,

924

925 **Heat Shock Proteins (Hsps)** – A family of proteins found in virtually all living  
926 organisms, produced by cells in response to exposure to high or low temperatures,  
927 as part of the heat shock response. Many Hsps function as chaperone proteins,  
928 stabilising the structure of other proteins which are sensitive to heat stress.

929

930 **Infertility/sterility** - Inability to produce viable offspring but can specifically mean  
931 inability to produce gametes.

932

933 **Lethal Temperature (LT)** - the temperature at which there is, for example, 80%  
934 (LT<sub>80</sub>) or 50% (LT<sub>50</sub>) mortality in a population/ set of experimental organisms, often  
935 measured similarly to a lethal dose response.

936

937 **Local Adaptation** - divergent selection leading to local populations having higher  
938 relative fitness under local environmental conditions.

939

940 **Microclimate** – a local set of atmospheric conditions that differ from those in the  
941 surrounding areas. Of interest to thermal biologists because of the potential to  
942 provide protection from temperature extremes. For example, animals may be able to  
943 shelter from high temperatures in burrows or shaded areas which stay cool.

944

945 **Operational Sex Ratio (OSR)** – the ratio of males to females within the mating pool  
946 (fertile and ready to mate).

947

948 **Polyspermy** – entrance of more than one sperm into the egg; typically lethal.

949

950 **Phenotypic plasticity** – the ability of a genome to produce multiple phenotypes  
951 depending on the environment.

952

953 **Reinforcement** – natural selection for reduced reproductive costs for hybrid  
954 reproduction increases reproductive isolation.

955

956 **Reproductive interference** – when reproductive isolation is incomplete and  
957 heterospecific individuals still engage in mating/reproductive activities, resulting in a  
958 fitness reduction for at least one of the interacting partners.

959

960 **Reproductive output** – a holistic term incorporating both fertility and fecundity.

961

962 **Thermal Fertility Limit (TFL)** - The temperature at which individuals become (at  
963 least temporarily) sterile (scored as a binary 0/1 outcome). As for LT, measured as  
964 TFL<sub>80</sub>/TFL<sub>50</sub>, the temperature at which either 80% or 50% of individuals in a  
965 population/ set of experimental organisms are infertile.

966

967 **Thermal Death Time (TDT)** - The integration of stress intensity (i.e. temperature)  
968 and exposure time. Through cumulative effects organisms for example may suffer  
969 more from a mildly stressful high temperature experienced for a long time versus an  
970 extreme temperature for a short time. As the relationship is exponential, a small  
971 increase in temperature may lead to a large decrease in tolerance time.

972 **Thermal Performance Curve (TPC)** - Graphical representation of the relationship  
973 between temperature and the value of a biological trait, for example how activity,  
974 climbing ability or offspring production change over a range of temperatures.

975  
976 **Thermal Sensitivity of Fertility (TSF)** - The relationship between temperature and  
977 reproductive output. The number of offspring produced or proxies thereof (e.g. sperm  
978 velocity, follicle number) are a measure of fertility rather than the binary 0/1 score of  
979 fertility.

980  
981 **Thermal Safety Margin (TSM)** - the difference between the thermal limit and the  
982 maximum ambient temperature experienced in the environment
