9 **Glaciers and ice sheets are important constituents of the Earth's land surface. Current**  
10 **worldwide retreat of glaciers has implications for the environment and for civilisation. There are**  
11 **a range of geomorphic changes occurring in cold environments and it is anticipated that these**  
12 **will be accentuated as a consequence of climate change. In particular, the number and size of**  
13 **proglacial lakes is currently increasing as a result of deglaciation and their significance for the**  
14 **physical environment and for society is becoming increasingly apparent. This article provides an**  
15 **overview of the major interdependent relationships between climate change, glaciers and**  
16 **proglacial lake development. In particular, it describes the key processes and impacts associated**  
17 **with proglacial lake evolution with reference to examples drawn from the European Alps, North**  
18 **America, the Himalayas, the Andes, Greenland, New Zealand and Iceland.**

19

## 20 **Our deglaciating planet**

21       Glaciers and ice sheets have advanced and retreated over time and their behaviour can be  
22 regarded as one of our barometers of climate change. Changing climate exerts a strong control on  
23 the nature and extent of glaciers and ice sheets and the extent and severity of glacial and  
24 periglacial processes. At the height of the Devensian glaciation 20,000 years ago, it is estimated  
25 that 30 % of the Earth's land surface was covered by ice. Today, Earth could still be regarded as a  
26 glacial planet if viewed from space, given that approximately 10 % of its land surface is currently  
27 occupied by ice. However, as is well known, glaciers and ice sheets have been generally retreating  
28 since the start of the twentieth century.

29       In most cold regions across the globe, glacier retreat and thinning has become accentuated  
30 over the last thirty years. This decline in ice mass has a range of implications for the natural  
31 environment and also for human society. Changes in slope stability, hydrological regimes and  
32 sediment fluxes have consequences for water security, power generation and the occurrence of  
33 natural hazards, thereby presenting challenges for society. One of the most obvious effects of

34 deglaciation is the increasing number and size of proglacial lakes. Understanding the character and  
35 development of proglacial lakes can provide insights into the behaviour of glaciers and ice sheets  
36 and help us to anticipate some of the impacts of present and future deglaciation. Such knowledge  
37 is important for the effective management of deglaciating environments; for example the  
38 monitoring of aquatic ecosystems and the management of water supplies and hydro-electric  
39 power generation. Better understanding of proglacial lake evolution is also critical for assessment  
40 of the hazards presented by such lakes; for example, glacial lake outburst flooding. In the next  
41 section, we define proglacial lakes and examine different lake types before discussing some of the  
42 processes and impacts of proglacial lake development.

43

#### 44 **Proglacial lakes - formation and evolution**

45 Proglacial lakes are masses of water impounded at the margin of an ice sheet or at the  
46 edge of a glacier. Proglacial lakes can be dammed by ice, bedrock, moraine or landslide debris or a  
47 combination of materials and the configuration and behaviour of such lakes is highly dependent  
48 on the nature of the surrounding environment (see Figure 1); in particular, the type of dam and its  
49 constituent materials strongly influence proglacial lake characteristics, lake evolution and lake  
50 drainage. Failure or overtopping of natural dams frequently leads to glacier lake outburst floods  
51 (GLOFS) or jökulhlaups, which are characterised by sudden-onset discharges that are far higher  
52 than those generated by snowmelt or rainfall in glacier systems. Jökulhlaups can be powerful  
53 agents of landscape change through erosion and sediment deposition and can present a hazard to  
54 people, ecosystems and infrastructure.

55

#### 56 ***Ice-dammed lakes***

57 The formation of lakes dammed by ice is usually a result of the thickening or advance of  
58 the damming ice margin, whether this is a glacier, an ice cap or an ice sheet. Ice-dammed lakes  
59 often form in tributary valleys where advance of a main valley glacier has obstructed river  
60 drainage or where tributary glaciers retreat from a junction with a main valley glacier (see Figure  
61 1). Sometimes anomalously rapid glacier advances, known as surges, can result in ice blocking  
62 tributary valleys and impeding drainage, thereby creating ice-dammed lakes; for example, the  
63 1986 surge of Hubbard Glacier Alaska, damming water in Russell Fjord. Ice-dammed lakes are  
64 strongly influenced by their proximity to ice and their evolution is frequently contingent on the  
65 nature of their relationship with it. Ice-dammed lakes exhibit cycles of lake formation, drainage,  
66 re-filling and re-emptying as the damming ice changes in thickness or as hydrological

67 characteristics of the dam vary; such changes influence the thresholds for triggering lake drainage  
68 along with the magnitude and frequency of floods. For example, during glacial advance, thickening  
69 ice dams impound larger amounts of water creating deeper lakes capable of generating periodic  
70 high magnitude jökulhlaups, whereas on ice retreat, thinner glacial dams retain gradually less and  
71 less water leading to smaller floods that occur on a more frequent basis. These lake filling and  
72 drainage cycles have implications for rates of erosion, sediment transfer and deposition along with  
73 the hazards that are caused by flooding.

74

#### 75 ***Moraine-dammed lakes***

76 Moraine-dammed lakes usually develop as a consequence of periods of glacier retreat or  
77 ice decay. When glaciers and ice sheets recede, water accumulates in topographic depressions  
78 formerly occupied by ice (see Figure 1) and the growth of lakes can be swift, sustained by  
79 precipitation and glacial meltwater. Debris-covered glaciers, prevalent in the Himalayas and New  
80 Zealand, are frequently the sites of moraine-dammed lakes as debris-covered glacier snouts  
81 stagnate. In these circumstances, buried ice can melt leaving depressions that rapidly fill with  
82 water and ice-cored moraine acts as effective damming material, although gradual melting of the  
83 ice core often leads to dam instability.

84 Moraine-dammed lake evolution is largely dependent on environmental setting. The  
85 dynamic evolution of debris-covered glaciers results in enlargement and deepening of moraine-  
86 dammed lakes as dead ice melts and subsides and sequences of lakes can develop at an ice margin  
87 often eventually coalescing to form one large lake. Ultimately, moraine-dammed lakes can  
88 become completely detached from ice. Over the last few decades, the identification and  
89 monitoring of moraine-dammed lakes has become increasingly important against a backdrop of  
90 glacier and ice sheet retreat. Moraine-dammed lakes have the potential to generate GLOFs as they  
91 expand; for example, if the dam loses integrity or there is a debris or ice fall into the lake  
92 generating a sufficiently powerful displacement wave, drainage of lake water may be initiated  
93 causing a jökulhlaup. There are numerous accounts of destructive floods from the moraine-  
94 dammed lakes of the Himalayas and the Andes and such events are likely to become more  
95 prevalent with rising numbers of lakes.

96

#### 97 ***Landslide and bedrock-dammed lakes***

98 Glacier retreat frequently results in slope instability as unconsolidated materials are  
99 exposed on valley sides which have previously been bolstered by glacial ice. Increased

100 precipitation and overland flow can lead to elevated pore water pressures in valley side materials,  
101 triggering valley side falls, flows and slides, all of which can obstruct drainage and lead to the  
102 ponding of water (see Figure 1). Landslide-dammed lakes are often transient since the materials  
103 forming the dam have poor cohesion and are easily eroded; once a landslide dam is overtopped,  
104 down-cutting can occur. Some proglacial lakes are dammed by bedrock, water accumulating in  
105 depressions revealed when glaciers retreat (see Figure 1); bedrock forms a much more stable and  
106 coherent damming structure than ice or unconsolidated sediments.

107

### 108 **Glacier dynamics and proglacial lake evolution**

109 Cycles of ice-dammed lake and moraine-dammed lake formation are strongly linked to  
110 glacier dynamics and glacier hydrology, in particular, patterns of advance and retreat, and ice  
111 thickening and thinning, which in turn can be linked to changing climate. Glacier margin  
112 morphology, physical stability and dynamics are affected by the presence, character and  
113 behaviour of an ice-marginal lake. The depth of water at an ice-margin determines (i) the distance  
114 'up-ice' that water propagates, (ii) vertical extension of a glacier's basal hydrological system via  
115 basal water pressure and (iii) ice calving rates. These factors encourage faster ice velocity and  
116 accentuate ice mass loss from a glacier system. Furthermore, ice-marginal lake water delivers heat  
117 to glacier ice and thus causes thermally-induced melting. Thermal melting can cause notches to  
118 develop at the water line and this thermal undercutting can strongly influence the rate of calving.  
119 The retreat of glaciers into over-deepened glacier basins often results in enhanced calving, which  
120 in turn generates positive feedback - calving causes lake expansion and further calving and ice  
121 retreat. Additionally heat delivery from ponded meltwater beneath and within a glacier,  
122 particularly in crevasses, also contributes to ice mass loss. Where ice-marginal lake water is  
123 sufficiently deep relative to the ice thickness, buoyancy will cause flotation of an ice margin and  
124 rapid calving, snout retreat and surface lowering, or sudden glacier lake drainage. Glacier ice that  
125 is grounded with lake water is often in tension and near fracture and consequently unstable. An  
126 ice-marginal lake will therefore cause glacier margin fluctuations, glacier velocity and glacier mass  
127 balance to be at least partially decoupled from climate.

128

### 129 **Proglacial lakes of the past**

130 The Quaternary record bears witness to the existence of proglacial lakes associated with  
131 alternating glacial and interglacial periods and there is abundant evidence of the impacts of

132 proglacial lakes associated with Pleistocene ice sheet deglaciation. Scrutiny of evidence from past  
133 proglacial lakes can assist us in anticipating future impacts.

134 The Quaternary ice sheet margins of northern Eurasia and central Asia dammed huge  
135 proglacial lakes, the drainage of which caused profound landscape change; for example,  
136 jökulhlaups from the Kuray and Chuya Basins, which drained through the Altai Mountains of  
137 southern Siberia. The emptying of lakes impounded at the margins of ice sheets in North America  
138 and northern Europe generated some of the largest floods on Earth, eroding great canyons and  
139 affecting ocean circulation and sediment fluxes both onshore and offshore. For example, there is  
140 extensive evidence of cycles of flooding from Glacial Lake Missoula which formed as a  
141 consequence of the deglaciation of the Cordilleran ice sheet in western Montana approximately  
142 15,000 years ago. Research suggests that this lake drained at least forty times and generated  
143 discharges over thirteen times that of the average discharge of the river Amazon; these  
144 catastrophic floods were responsible for the sculpting of the Channelled Scablands of Washington  
145 State and for the deposition of huge quantities of fine-grained sediments in Washington and  
146 Oregon. The emptying of Glacial Lake Agassiz formed in association with the deglaciation of the  
147 Laurentide Ice Sheet has also been comprehensively researched.

148 The vast majority of Quaternary proglacial lake basins have flat floors produced by  
149 voluminous sedimentation. Terrain that was previously glacially subdued and smoothed can  
150 become draped and obscured by thin beds and laminae of silts and clays. Proglacial lake basins,  
151 such as those in the Hudson Bay area and on the Canadian Shield, can also be recognised today as  
152 very extensive areas of peatlands that have accumulated due to relatively impermeable sediments  
153 and poor drainage. These palaeo-lake areas are usually further distinguished by encircling wave-  
154 cut cliffs or by coarser sediment that was deposited in shallower water, such as beaches and lags  
155 of wave-washed sediment. On a large scale, bathymetry of proglacial lakes is dependent on  
156 regional topography. Very large Pleistocene proglacial lakes across North America developed at  
157 least partly because the continental land surface slope trended northwards towards the Arctic  
158 Ocean. This slope, which was inverse to the direction of ice motion, was accentuated by isostatic  
159 depression and thus a considerable accommodation space for meltwater was created in the  
160 landscape.

161 In addition to modifying the physical landscape, the development of a range of  
162 physiographic features as a consequence of deglaciation at the end of the Pleistocene would have  
163 had a profound effect on early explorers and settlers; this has been particularly commented upon  
164 in relation to human settlement of the North American interior. There is some evidence that large

165 proglacial lakes and boggy ground formed by gradually deglaciating terrain may have acted as  
166 barriers to recolonization by large mammals and humans. However, it has also been suggested  
167 that the presence of proglacial lakes may have encouraged migration by providing resources and  
168 easy routes through the terrain, with some such locations being used as staging posts from which  
169 further exploration and settlement could be supported.

170

### 171 **Current distribution of proglacial lakes**

172 The number and size of proglacial lakes around the world has been increasing as a  
173 consequence of deglaciation and we anticipate further growth over the coming decades. For  
174 example, research has identified expanding proglacial lakes in the European Alps, Norway, Iceland,  
175 Greenland, the Caucasus Mountains, Alaska, New Zealand, Canada, South America and across the  
176 Himalaya. Many regions are exhibiting complex patterns of proglacial lake development and  
177 behaviour as lakes grow, coalesce and drain. Some ice-dammed lakes have evolved into moraine-  
178 dammed lakes as they gradually separate from glacial ice. In any one glacier system, there may be  
179 a number of lakes dammed by different materials filling and draining. Figure 2 illustrates some  
180 examples of the rapid development of proglacial lakes in response to deglaciating conditions; we  
181 comment particularly on examples from Iceland and New Zealand below.

182 In Iceland, proglacial lake formation has accelerated over the last 15 years, particularly  
183 around the southern outlet glaciers of the Mýrdalsjökull and Vatnajökull ice caps. At  
184 Breiðamerkurjökull, the proglacial lake Jökulsárlón has been developing since 1934 and is now 18  
185 km<sup>2</sup> in surface area (Figure 3). Proglacial lakes have been developing rapidly at Skaftafellsjökull,  
186 Svínafellsjökull, Heinabergsjökull, and Fláajökull as a consequence of glacier retreat into  
187 overdeepened glacial troughs; some of these troughs extend up to 300m below sea level, implying  
188 that proglacial lakes are likely to expand further with continued retreat. At the margins of the  
189 piedmont glacier Skeiðarárjökull, small proglacial lakes have grown larger and coalesced. At  
190 Mýrdalsjökull ice cap to the south-west of Vatnajökull, the outlet glacier Sólheimajökull has  
191 exhibited retreat from 1995 onwards accompanied by the growth and coalescence of proglacial  
192 lakes (Figure 4). The current glacier retreat rate here is approximately 100m each year.

193 In New Zealand, there has been significant retreat of the glaciers of the Southern Alps, and  
194 this retreat has accelerated over the last ten years. The Tasman Glacier is currently retreating by  
195 approximately 450 to 800 metres each year and terminates in a proglacial lake ~ 8 km in length, 2  
196 km in width and > 200 m in depth. This lake did not exist in 1973. Nearby Hooker and Mueller  
197 Glaciers also terminate in proglacial lakes, which are similarly expanding. A scenario envisaged for

198 the near-future evolution of Hooker Glacier lake sees stabilisation when glacier ice velocity equals  
199 calving rates, but only when the glacier retreats more than 3 km up-valley from the Hooker Lake  
200 outlet after 2028.

201

### 202 **Landform and sedimentary impacts of proglacial lakes**

203 The spatially and temporally complex behaviour of proglacial lakes has a range of impacts  
204 on the geomorphic environment. As glaciers and ice sheets retreat, they reveal sediments on  
205 valley sides that are then subject to paraglacial slope readjustment and sediment fluxes from  
206 glacial systems tend to increase as a consequence. However, the presence of proglacial lakes  
207 disrupts the flow of meltwater from glaciers and ice sheets resulting in sedimentation, as flow  
208 velocities are retarded on entry into lake basins. Sediments that would otherwise be transported  
209 into and beyond the proglacial zone therefore become trapped and stored with proglacial lakes,  
210 which act sediment sinks. Investigations have established that the presence of proglacial lakes in  
211 Patagonia interrupted Pleistocene dust flux to Antarctica by trapping fine-grained sediment.  
212 Research on both Quaternary and modern proglacial lake sedimentation within particular  
213 catchments demonstrates that evidence of the variability of sediment fluxes can be derived from  
214 proglacial lake sediments and that lake sediments can be used to infer regional hydrologic changes  
215 and also variations in climate. In these ways, information from the analysis of existing lakes can be  
216 used to help us predict what accompanying changes might occur as other lakes form. Over the  
217 next decades, it is predicted that many developing proglacial lakes will fill with sediments released  
218 from glacial systems as a consequence of present deglaciation.

219 Sudden drainage of ice, moraine and landslide-dammed lakes results in extremely rapid  
220 and intense erosion, transportation and deposition of vast amounts of sediment. This sediment  
221 transport creates spectacular landforms including deep canyons and gorges, huge ripples, boulder  
222 bars and fans of sediment, examples of which can be seen in the landscapes of the Altai  
223 Mountains of south-central Siberia and the Channelled Scablands of Washington State.

224

### 225 **Proglacial lake and climate interactions**

226 It is clear that glaciers and ice sheets are responding to a warming climate through retreat,  
227 and that the development of proglacial lakes is one such response; however, the relationships  
228 between ice, the development of proglacial lakes and climate are more complex than this. The  
229 effects of large late-Pleistocene proglacial lakes have been modelled and their presence is thought  
230 to have resulted in cooler summers and attendant ice sheet growth, actually delaying ice sheet

231 decay. The drainage of large Quaternary proglacial lakes, such as Lake Agassiz, has been  
232 extensively researched and has been demonstrated to have disrupted the salinity gradient that  
233 drives meridional overturning circulation, thereby cooling climate due to the sudden inflow of  
234 huge amounts of meltwater into the oceans. It is thought that discharges from such lakes could  
235 have reached in excess of one million cubic metres per second; as a comparator, the average  
236 discharge of the Amazon River is approximately one fifth of this, at two hundred thousand cubic  
237 metres per second. Research is ongoing, but it has been suggested that the development and  
238 drainage of huge proglacial lakes in Eurasia could also have perturbed regional hydrological  
239 conditions and thereby affected global climate. Although most currently forming proglacial lakes  
240 are at present too small to generate climate feedbacks, they can affect local environmental  
241 conditions through the absorption of incoming shortwave radiation in summertime and its  
242 reflection in the winter. Figure 5 illustrates the principal interactions between climate, glaciers and  
243 proglacial lakes, summarising some of the above discussion.

244

#### 245 **What can we expect in the future?**

246 Global climate warming is resulting in substantial glacier and ice sheet retreat. The  
247 development of proglacial lakes as a consequence of ice retreat presents a number of issues for  
248 society looking forward into the rest of this century and beyond. The drainage of proglacial lakes  
249 can result in hazardous jökulhlaups, which cause substantial landscape change. The growth of  
250 proglacial lakes also presents opportunities and challenges for water security, both in the context  
251 of potable water supplies and water for irrigation and power generation. Further research will be  
252 needed to increase understanding of the response of ocean circulation to freshwater inputs and  
253 the extent to which the drainage of large proglacial lakes can perturb normal patterns of ocean  
254 circulation and stimulate climate fluctuations, given the development of proglacial lakes triggered  
255 by current deglaciation. Monitoring of the temporal and spatial evolution of proglacial lakes and  
256 their characteristics will be vital to scientific understanding and to develop effective and  
257 sustainable ways of living with anticipated changes. Integrating the detection and monitoring of  
258 proglacial lakes with physical analyses and socio-economic data remains a key objective for the  
259 future.

260

#### 261 **Summary**

262 Climate change and associated glacier retreat are having profound impacts on cold  
263 environments; these impacts have geomorphological and societal consequences. Proglacial lakes

264 are increasing in number and size around the world. It is clear that the study of proglacial lakes  
265 and their spatial and temporal development can help us to understand the effects of past  
266 deglaciation and to predict some of the likely impacts of future deglaciation. Understanding the  
267 formation and evolution of proglacial lakes reveals a number of key processes and  
268 interdependencies.

269 In a geomorphic context, proglacial lakes can act as buffers between glaciers and the  
270 proglacial zone, interrupting the flow of meltwater and sediment from glaciers to the oceans. This  
271 influences spatial and temporal patterns of erosion, transportation and deposition of sediments in  
272 de-glaciating environments. We can examine sediments contained within proglacial lakes in order  
273 to establish records of past environmental change and to predict the impacts of future changes.  
274 Ice-dammed and moraine-dammed lake filling and draining cycles influence the geomorphic  
275 impact of such lakes, affecting the rate of erosion, deposition and landscape development.

276 Some proglacial lakes have marked influences on glacier and ice sheet dynamics; for  
277 example, ice contact lakes affect the stability and character of glacier margins through calving.  
278 Proglacial lakes can influence climate and can be influenced by it. The presence of large proglacial  
279 lakes during the Pleistocene is thought to have cooled regional climate and retarded ice sheet  
280 decay. More widely, it has been established that jökulhlaups from proglacial lakes can modify  
281 ocean circulation and climate through the delivery of freshwater and sediment in large quantities.  
282 The shift from glaciers terminating on land to glaciers terminating in proglacial lakes is a defining  
283 point in deglaciating environments. We expect that proglacial lakes will continue to increase in  
284 number and size due to glacier thinning and retreat; their existence and expansion will have a  
285 number of fundamental effects, including perturbing glacier dynamics, modulating proglacial  
286 meltwater and sediment fluxes and presenting potential hazards.
