## Abstract

When natural gas is port/manifold injected into a compression ignition engine, the mixture of air and the natural gas is compressed during the compression stroke of the engine. Due to the difference in the values of specific heat capacity ratio between air and natural gas, the temperature and pressure at the time of pilot fuel injection are different when compared to a case where only air is compressed. Also, the presence of natural gas affects the peak in-cylinder (adiabatic flame) temperature. This significantly affects the performance as well as emissions characteristics of natural gas based dual fueling in CI engine. Natural Gas has been extensively tested in a single cylinder

compression ignition engine to obtain performance and emissions maps. Two pilot fuels, diesel and RME, have been used to pilot natural gas combustion. The performance of the two liquid fuels used as pilots has also been assessed and compared. Tests were conducted at 48 different operating conditions (six different speeds and eight different power output conditions for each speed) for single fueling cases. Both the diesel and RME based single fueling cases were used as baselines to compare the natural gas based dual fueling where data was collected at 36 operating conditions (six different speeds and six different power output conditions for each speed). Performance and emissions characteristics were mapped on speed vs brake power plots. The thermal efficiency values of the natural gas dual fueling were lower when compared to the respective pilot fuel based single fueling apart from the highest powers. The effect of engine speed on volumetric efficiency in case of the natural gas based dual fueling was significantly different from what was observed with the single fueling. Contours of specific  $\text{NO}_x$  for diesel and RME based single fueling differ significantly when these fuels were used to pilot natural gas combustion. For both of the single fueling cases, maximum specific  $\text{NO}_x$  were centered at the intersection of medium speeds and medium powers and they decrease in all directions from this region of maximum values. On the other hand, an opposite trend was observed with dual fueling cases where minimum specific  $\text{NO}_x$  were observed at the center of the map and they increase in all direction from this region of minimum  $\text{NO}_x$ . RME piloted specific  $\text{NO}_x$  at the highest speeds were the only exception to this trend. Higher specific HC and lower specific  $\text{CO}_2$  emissions were observed in case of natural gas based dual fueling. The emissions were measured in g/MJ of

engine power.

## 2 1. Introduction

Natural gas has long been considered an alternative fuel for the transportation sector and has been used to fuel vehicles since the 1930's. Natural gas is the cleanest fossil fuel available and its proven reserves are 5288.5

6 trillion cubic feet, much larger than crude oil [1]. Low carbon content and  
7 clean burn features (low soot and smoke) have helped the proliferation of  
8 natural gas as an alternate fuel with the introduction of ever more strin-  
9 gent emissions standards. Natural gas has properties that are very similar  
10 to those of methane ( $\text{CH}_4$ ), which is its primary constituent. It also contains  
11 heavier hydrocarbons such as ethane ( $\text{C}_2\text{H}_6$ ), propane ( $\text{C}_3\text{H}_8$ ), and butane  
12 ( $\text{C}_4\text{H}_{10}$ ), and inert diluents such as molecular nitrogen ( $\text{N}_2$ ) and carbon diox-  
13 ide ( $\text{CO}_2$ ) [3–6].

14 Natural gas has a low cetane number (compared to diesel fuel) [2, 5, 6],  
15 but it has a high specific heat capacity ratio  $\gamma$  (when compared with air). The  
16 poor ignition characteristics (extended ignition delay) of low cetane number  
17 fuels in CI engines often prevents ignition entirely at the temperatures found  
18 under compression in a CI engine.

19 Various ignition strategies are used to ignite natural gas in unmodified CI  
20 engines. A high cetane liquid fuel such as diesel [6–8] or RME [6] have been  
21 widely used as an initial source of ignition using the dual fuel concept [9].  
22 The natural gas is most often inducted into the engine in the air intake  
23 manifold with the high cetane fuel directly injected into the cylinder. To  
24 ensure ignition and sustain acceptable combustion there is a lower limit of  
25 the quantity of the high cetane fuel that must be injected [9].

26 The adiabatic flame temperature of methane in air for  $\phi=1$  and  $\phi=0.5$   
27 have been presented by Karim [14]. Assuming an initial temperature of  
28 around 800K at TDC, the difference in peak temperature (adiabatic flame  
29 temperature) between the methane mixture of  $\phi=1$  and  $\phi=0.5$  is in ex-  
30 cess of 600K. The effect of difference in the specific heat capacity ratios of

31 air and natural gas, on the in-cylinder temperature at the end of compres-  
32 sion, can be evaluated by using a freely available program REFPROP [15].  
33 When a sample calculation is made at a pressure of 2.5 MPa and a temper-  
34 ature of 500K, it yields  $\gamma=1.3559$  for air and  $\gamma=1.3985$  for a stoichiometric  
35 mixture of methane and air. With inlet temperature ( $T_1$ ) set at 300K, the  
36 peak compression temperature ( $T_2$ ) can be calculated by using the following  
37 relationship

$$T_2 = T_1 \cdot r_c^{(\gamma-1)} \quad (1)$$

38 where  $r_c$  is the compression ratio of the engine used in these tests. The  
39 peak compression temperatures calculated in this manner are 837K for air  
40 and 750K for the stoichiometric methane/air mixture. As analyzed above,  
41 the presence of natural gas reduces the peak temperature by 100K and the  
42 adiabatic flame temperature by 500K

43 The higher specific heat capacity ratio of natural gas lowers in-cylinder  
44 charge temperature and increases ignition delay compared to the baseline  
45 diesel operation and hence is critical from an emissions perspective [10, 11].  
46 Due to these competing factors dual fueling with natural gas needs to be  
47 investigated across a wider range of engine operating conditions to assess  
48 the affect of engine speed and load (power output) in addition to the above  
49 mentioned factors.

50 Dual fueling of CI engine with natural gas has demonstrated a slight re-  
51 duction of brake thermal efficiency when compared to fueling with standard  
52 mineral diesel [7, 8, 12–14] whereas higher thermal efficiency values were re-  
53 ported at higher loads [16]. Concerning total brake specific fuel consumption,  
54 it is revealed that it becomes inferior under dual fuel operation compared to

55 normal diesel operation at the same engine operating conditions because of  
56 the smaller heating value of natural gas. At high load, the values of total  
57 brake specific fuel consumption under dual fuel operation tend to converge  
58 with that of normal diesel operation [7].

59  $\text{NO}_X$  is strongly dependent on local temperatures so most  $\text{NO}_X$  is ex-  
60 pected to form in the region around the pilot spray where high temperatures  
61 exist and the equivalence ratio is close to stoichiometric [17]. Earlier and  
62 faster combustion events increase the duration for which in-cylinder condi-  
63 tions are suitable for  $\text{NO}_X$  formation [18]. The use of natural gas under dual  
64 fueling in CI engines significantly affect  $\text{NO}_X$  emissions: the  $\text{NO}_X$  concen-  
65 tration under dual fuel operation is lower when compared to normal diesel  
66 operation. At the same time, a significant decrease in soot emissions un-  
67 der dual fuel operation has also been reported [3]. On the other hand, CO  
68 and HC emissions levels have been reported to be considerably higher when  
69 compared to normal diesel operation [7, 10–12, 19].

70 Whereas literature has been reported on natural gas combustion and  
71 emissions under dual fueling conditions in CI engines, most of the studies  
72 lack one or the other important aspects. The studies are either restricted  
73 to various loads/powers at one engine speed (neglecting the effect of engine  
74 speed) or one or two load/power conditions at various speeds (neglecting  
75 load variations). There is a scarcity of engine “fuel maps” in the open liter-  
76 ature (these are the full contours of thermal efficiency or brake specific fuel  
77 consumption plotted throughout the power vs speed range of the engine, or  
78 the torque vs speed range of the engine). Sample fuel maps can be found  
79 in [20–22]. One such plot of thermal efficiency contours with dual-fueling has

80 been presented previously to demonstrate the thermal efficiency within the  
81 operating range of the test engine used in this paper [11]. Maps showing the  
82 thermal efficiency as well as specific emissions contours on the power-speed  
83 plots are seldom found in the open literature [23].

84 The choice of pilot fuel has also been limited to either diesel or biodiesel  
85 only and the performance of these two pilots has hardly been investigated and  
86 compared over a wider range of operating conditions in compression ignition  
87 environment. The study presented here is an effort to fill these gaps in the  
88 literature available on natural gas based dual fueling in CI engines.

89 A specific engine model may be used as a power source for many different  
90 applications, each with its own different load characteristics. For instance  
91 the same engine can be used to power: two different-size cars; a small marine  
92 vessel; an electricity generator; and in several other applications. The pro-  
93 cedure of selecting the engine (prime mover) while considering the engine's  
94 contours of thermal efficiency on the power-speed range of the engine, and  
95 concurrently the load line of the powered device, has been briefly described  
96 in [6]. Much of the automotive sales literature available will quote the max-  
97 imum torque at one engine speed, maximum power at another engine speed  
98 (though the engine may be rarely operating at these conditions), and the av-  
99 erage fuel consumption and total emissions over one or two strictly-specified  
100 drive cycles (which may or may not be representative of the intended use of  
101 the buyer). In research papers laboratory experiments of engine performance  
102 and emissions are usually conducted at constant equivalence ratio, or con-  
103 stant brake mean effective pressure, or occasionally at constant speed. All  
104 of these representations are of some use to the average consumer, but they

105 do little to represent or explain the overall thermal efficiency and emissions  
106 characteristics of engines throughout their operating range.

107 In the work presented in this paper both speed and power are consid-  
108 ered for diesel and RME piloted natural gas combustion in a direct injection  
109 CI engine. The results are presented as iso-contours of thermal efficiency,  
110 volumetric efficiency and brake specific emissions on a power-speed graph  
111 throughout the operating range of the engine. The engine is a standard  
112 test engine, typical of the majority of such engines used in the developing  
113 economies of the world; and though more-modern engines may have higher  
114 thermal efficiency and lower emissions, the shape and regions of contours  
115 presented in this paper are representative of those shapes for typical CI en-  
116 gines and are applicable to all engine performance and emissions contours.  
117 This is a novel approach to representing these data, especially for CI en-  
118 gines. As one example of the utility of the considerations presented in this  
119 paper, the specific  $\text{NO}_X$  emissions contours presented later illustrate that  
120 for the baseline single-fuel diesel configuration the region of high specific  
121  $\text{NO}_X$  emissions is at intermediate engine speed and power, dropping off at  
122 high and low values of engine speed and power, helping to explain the  $\text{NO}_X$   
123 emission trends presented elsewhere in the literature; while the dual-fueling  
124 specific  $\text{NO}_X$  emissions contours show monotonically increasing trends with  
125 increasing engine load and increasing engine speed.

## 126 **2. Experimental Set Up**

127 A four-stroke single-cylinder Gardner 1L2 compression ignition engine  
128 was used, the specifications of which are shown in Table 1. Fig1 illustrates

Table 1: Specifications of the Gardner 1L2 diesel engine and Characteristics of RME used

No. of cylinders	1
Bore	107.95mm
Stroke	152.40mm
Swept volume	$1394 \times 10^{-6} m^3$
Clearance volume	$115.15 \times 10^{-6} m^3$
Compression ratio	13.11:1
Max. power	11kW @ 1500rev/min
NO. of nozzle holes	4
Diameter of the nozzle hole	$200 \times 10^{-6} m$
IVO	10°BTDC
IVC	40°ABDC
EVO	50°BBDC
EVC	15°ATDC
Heating value of RME	38MJ/Kg
Density of RME	$880 kg/m^3$
Cetane number of RME	54.4
Chemical Formula of RME	$C_{21}H_{38}O_2$

129 the schematic layout of the experimental rig showing hydraulic brake, fuel  
 130 supply lines, various emission analyzers and instrumentation. The engine has  
 131 been used to test natural gas (current study) and hydrogen in dual fueling  
 132 mode.

133 Pilot fuels are injected directly into the cylinder through the standard  
 134 engine fuel system. Natural gas is supplied from the mains supply passing  
 135 through a solenoid valve, two ball valves and two diaphragm valves. The

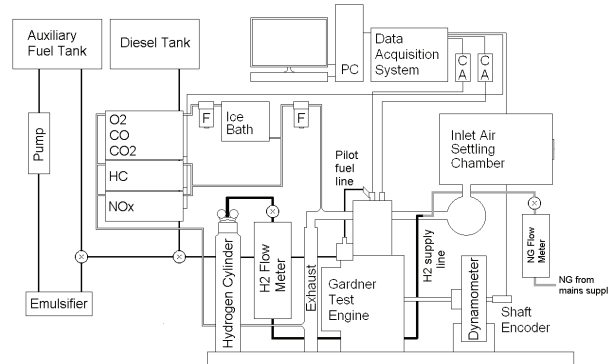

Figure 1: Experimental rig of dual-fueled CI engine

136 gas then flows through a natural gas flow meter (0-100 liter/min scale) to be  
 137 inducted into the engine air inlet manifold via a stainless steel tube along with  
 138 the incoming air under the engine's own suction. The resultant mixture that  
 139 is inducted into the cylinder is considered to be a homogeneous mixture of  
 140 natural gas and air. Air flow measurements are made using using an inclined  
 141 manometer measuring the pressure drop across an orifice plate fitted to a  
 142 large settling tank in the engines intake system.

143 For normal CI engine operation, the load placed on the engine started at  
 144 0.126 MPa brake mean effective pressure (BMEP) and went up to 0.566 MPa  
 145 BMEP in 0.126 MPa increments. 0.566 MPa is the maximum achievable  
 146 BMEP with this mains supply of natural gas. During natural gas dual-  
 147 fuel operation the amount of pilot fuel injected is set at a flow rate providing  
 148 0.126 MPa BMEP during normal engine operation. The engine power output  
 149 is then increased further by adjusting the flow rate of natural gas inducted  
 150 by the engine to reach the high power regions.

151 A Signal 4000VM chemiluminescence analyzer is used to measure wet  
 152  $\text{NO}_X$  emission volume concentrations, while wet unburnt hydrocarbon (HC)

153 emission volume concentrations are measured by a Rotork Analysis model  
154 523 flame ionization detector (FID) analyzer (both analyzers sampled ex-  
155 haust gas via a heated line at 160°C). A Servomex 4210C exhaust gas ana-  
156 lyzer measured dry volume concentrations of carbon monoxide (CO), carbon  
157 dioxide (CO<sub>2</sub>) and oxygen (O<sub>2</sub>) concentrations using non-dispersive infra-  
158 red sensors and a paramagnetic sensor respectively.

159 The results were calculated as described in previous publications [11, 24].  
160 Contours of thermal efficiency and emissions were plotted on brake power vs  
161 engine rotational speed (r/min) figures.

### 162 **3. Pressure and rate of energy release data on selected operating** 163 **conditions**

164 This section presents pressure and rate of energy release data to support  
165 the claims made in the following section. Figures 2(a) and 2(b) present the  
166 in-cylinder pressure and the rate of energy release for diesel and RME fuelling  
167 at a BMEP of 0.125 MPa while operating at 1000 rev/min. Figures 3(a)  
168 and 3(b) present the in-cylinder pressure and the rate of energy release for  
169 diesel and RME fueling at a BMEP of 0.503 MPa while operating at 1000  
170 rev/min. While operating at lower load, higher peak in-cylinder pressure has  
171 been observed when compared to RME. Shorter ignition in case of RME has  
172 caused the peak pressure to occur slightly earlier. When the rate of energy  
173 release curves for the two fuels were compared, diesel has shown clearly higher  
174 rate of energy release peaks. Both peaks for the rate of energy release higher  
175 lower and occur earlier when compared to the ones obtained with diesel. At  
176 higher loads, the two fuels have shown similar peak pressures with diesel

Figure 2: Experimentally obtained in-cylinder pressure (a) and rate of energy release (b) for diesel and RME at a BMEP of 0.125 MPa and 1000 rev/min

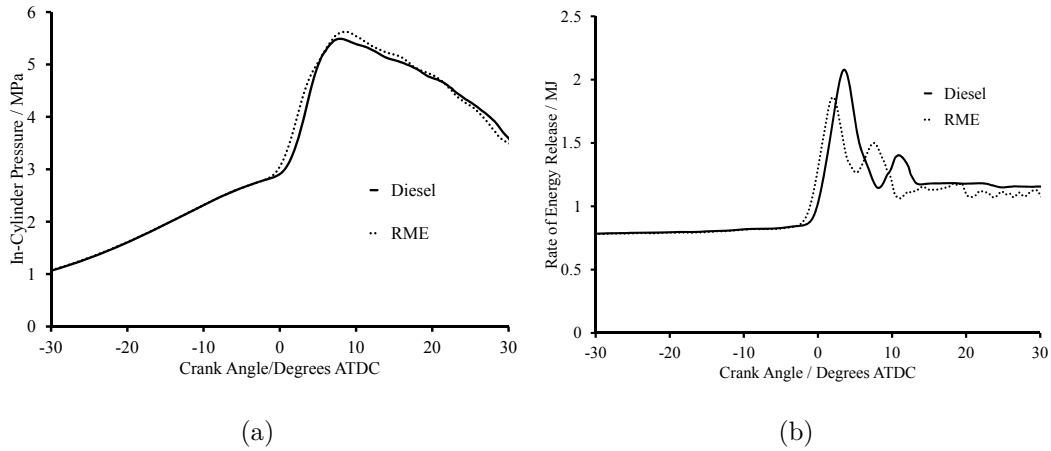

Figure 3: Experimentally obtained in-cylinder pressure (a) and rate of energy release (b) for diesel and RME at a BMEP of 0.503 MPa and 1000 rev/min

177 producing slightly higher peak pressure but the difference in peak pressures  
 178 for the two fuels is reduced when compared to the lower load case.  
 179 Similar to the lower load case, the first rate of energy release peak diesel is  
 180 significantly higher but the second peak for RME is higher when compared

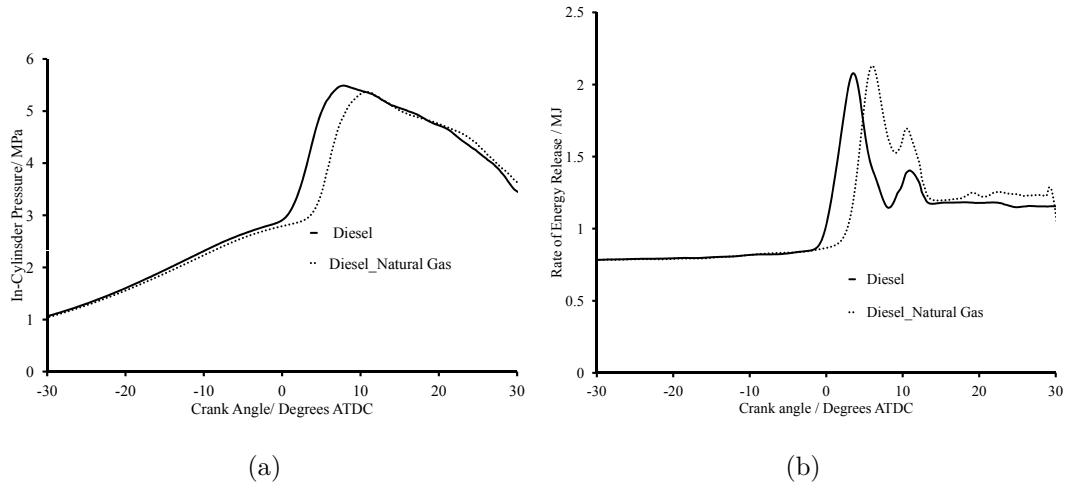

Figure 4: Experimentally obtained in-cylinder pressure (a) and rate of energy release (b) for pure diesel and diesel piloted natural gas at 0.503 MPa with diesel pilot set at 0.125 MPa for the dual fueling case 1000 rev/min

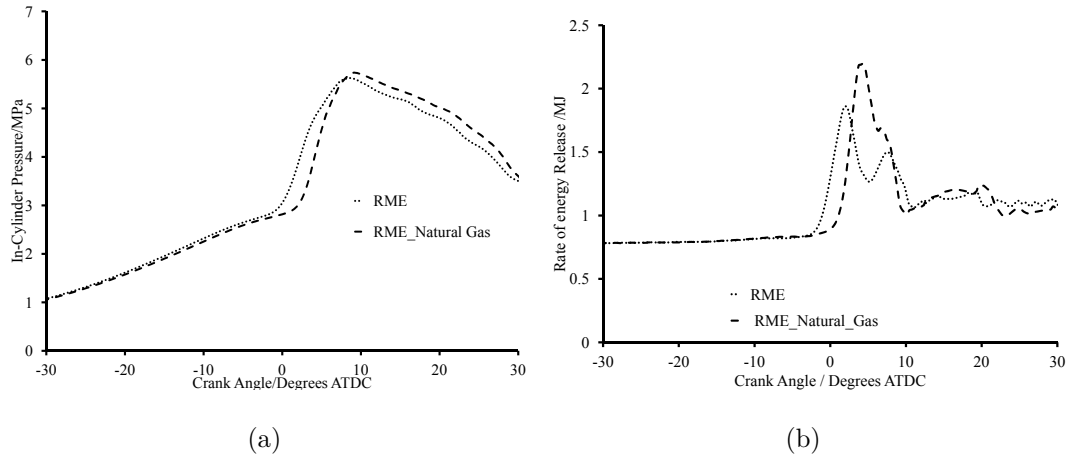

Figure 5: Experimentally obtained in-cylinder pressure (a) and rate of energy release (b) for pure RME and RME piloted natural gas at 0.503 MPa with diesel pilot set at 0.125 MPa for the dual fueling case 1000 rev/min

181 to the second peak obtained with diesel at the higher load.

182 Figures 4(a) and 4(b) in-cylinder pressure and rate of energy release for

183 pure diesel and diesel piloted natural gas at 0.503 MPa with diesel pilot set  
184 at 0.125 MPa for the dual fuelling case 1000 rev/min. At a relatively lower  
185 load (0.38 MPa), diesel piloted natural gas has produced lower peak pressure  
186 when compared to the pure diesel based single fueling whereas similar peak  
187 pressures are observed when the two cases are compared at a higher BMEP  
188 (0.503 MPa). The rate of energy release peaks for the dual fueling case  
189 are comparable to the ones obtained with diesel based single fueling but  
190 these occur slightly later in the cycle. Figures 5(a) and 5(b) present the  
191 in-cylinder pressure and the rate of energy release for pure RME and RME  
192 piloted natural gas at 0.503 MPa with RME pilot set at 0.125 MPa for the  
193 dual fueling case 1000 rev/min. RME based dual fueling of natural gas has  
194 exhibited similar peak pressure but clearly higher first rate of energy release  
195 peak when compared to the RME based single fueling.

#### 196 **4. Results and discussion**

197 This section has been divided into two parts. The first half presents  
198 and discusses the experimentally obtained maps of different performance and  
199 emissions parameters for diesel piloted dual fueling of natural gas and com-  
200 pares these maps with those obtained in diesel based single fueling mode.  
201 The second half presents and discusses the experimentally obtained maps of  
202 different performance and emissions parameters for RME piloted dual fueling  
203 of natural  
204 gas and compares these maps with those obtained in RME based single  
205 fueling mode.

206 *4.1. Diesel Plus NG*

207 Maps for thermal efficiency, volumetric efficiency, specific  $\text{NO}_x$ , specific  
208 HC and specific  $\text{CO}_2$  have been presented for diesel based single fueling and  
209 diesel piloted dual fueling of natural gas.

210 *4.1.1. Thermal and volumetric Efficiency*

211 Fig. 6(a) presents an experimentally obtained map showing iso-contours  
212 of thermal efficiency for diesel based single fueling whereas Fig. 6(b) presents  
213 a similar map for diesel piloted dual fueling of natural gas.

214 While operating in dual fuel mode using diesel-ignited natural gas no sig-  
215 nificant difference (overall) is observed in thermal efficiency when compared  
216 to pure diesel operation. At higher power outputs, dual fuel mode produces  
217 similar or higher thermal efficiencies as compared to normal fueling mode  
218 whereas at relatively lower power outputs, lower values of thermal efficiency  
219 have been observed (Fig. 6(b)).

220 The lower thermal efficiency values at lower power may be attributed  
221 to the failure of pilot fuel to ignite and sustain adequate combustion of the  
222 natural gas-air mixture. Whilst the local equivalence ratio in the region of  
223 the pilot injection may be near unity (stoichiometric), especially during the  
224 initial pre-mixed combustion phase, the overall F/A ratio is 0.25% lower  
225 than single diesel fueling at the lower power output. This suggests that  
226 the portion of the combustion chamber not in the pilot region contains a  
227 lean homogeneous mixture of natural gas and air. At the highest power  
228 outputs the dual fuel mode exhibits a F/A ratio 3.73% higher than that  
229 of single diesel fueling. Under these conditions the pilot fuel is igniting a  
230 richer homogenous mixture resulting in a 3.1% (approximately) increase in

(a) Thermal Efficiency - Diesel

(b) Thermal Efficiency - Diesel Plus NG

Figure 6: Experimentally obtained thermal efficiency contours of diesel single fueling (a) and diesel piloted natural gas dual fueling (b)

231 thermal efficiency. As the power output increases the dual fuel mode recovers  
 232 the thermal efficiency losses suffered at the lower power outputs with both  
 233 modes of operation having similar  $F/A$  ratios.

234 Fig. 7(a) presents an experimentally obtained map showing volumetric ef-

(a) Volumetric Efficiency - Diesel

(b) Volumetric Efficiency - Diesel Plus NG

Figure 7: Experimentally obtained volumetric efficiency contours of diesel single fueling (a) and diesel piloted natural gas dual fueling (b)

235 efficiency trends on a speed-power graph for diesel based single fueling whereas  
 236 Fig. 7(b) presents a similar map for diesel piloted dual fueling of natural gas.  
 237 The volumetric efficiency map (Fig. 7(b)) reflects the lower values for dual  
 238 fuel mode. This is to be expected as a portion of the inducted air is being  
 239 displaced by the natural gas in the intake, reducing the air partial pressure

240 below that of the mixture pressure. Also as to be expected is the drop of  
241 volumetric efficiency as the engine speed increases for both modes of opera-  
242 tion (Fig. 7(a) and 7(b)). The frictional losses in the air intake are known  
243 to increase as the square of engine speed [22] . The slope of the volumetric  
244 efficiency contours is flatter for natural gas dual fueling with diesel than for  
245 baseline diesel operation and the values are lower. This is a consequence of  
246 the method used to introduce natural gas into the engine. As the natural  
247 gas has been introduced via manifold injection, a portion of the intake air  
248 is displaced by the natural gas, reducing the measured volume flow rate of  
249 air into the engine. This leads to a reduction of the engine's volumetric flow  
250 rate. The slope of the iso-contours differs due to a change in the scaling of  
251 volumetric efficiency with engine speed. As the amount of natural gas added  
252 is increased to meet the increase in speed demand, larger amounts of air are  
253 displaced. As the natural gas is introduced at the manifold and does not flow  
254 through the entire intake system but the air does, the scaling law as noted  
255 by Heywood [22] does not hold.

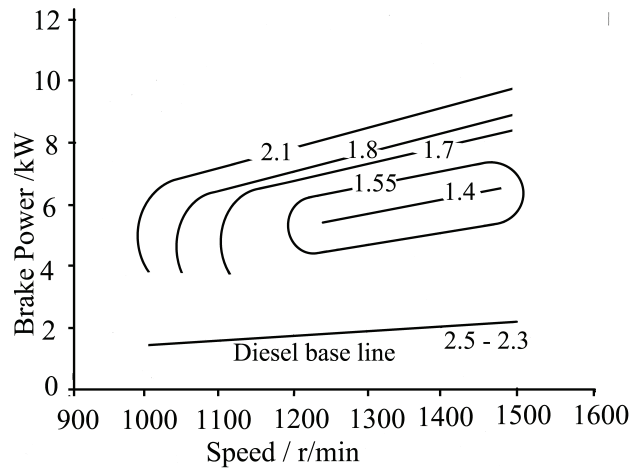

#### 256 4.1.2. Specific $NO_X$

257 Fig. 8(a) presents an experimentally obtained map showing iso-contours  
258 of specific  $NO_X$  for diesel based single fueling whereas Fig. 8(b) presents a  
259 similar map for diesel piloted dual fueling of natural gas. Significant reduc-  
260 tion in  $NO_X$  is noted with diesel piloted natural gas dual fueling compared  
261 to diesel single fueling.

262 The composition of the in-cylinder mixture prior to combustion in case of  
263 dual fueling is different from that during diesel single fueling. In case of single  
264 fueling the major constituent of the in-cylinder mixture during compression

(a) Specific NO<sub>x</sub> /g/MJ - Diesel

(b) Specific NO<sub>x</sub> / g/MJ - Diesel Plus NG

Figure 8: Experimentally obtained specific NO<sub>x</sub> contours for diesel single fueling (a) and diesel piloted natural gas dual fueling (b).

265 stroke is air along with a fraction of the residual gases from the previous  
 266 combustion event. Whereas in case of dual fueling, the mixture during com-  
 267 pression stroke is composed of a homogeneous mixture of air , natural gas  
 268 and residual gases. Fig. 9 shows the variation of the specific heat at constant

269 pressure with temperature for air and methane ( main constituent of natu-  
270 ral gas) and Fig. 10 shows enthalpy contribution of natural gas at different  
271 operating conditions.

272 The specific heat capacity ratio of natural gas is significantly higher than  
273 for air. An overall increase in the heat capacity of the in-cylinder mixture as  
274 is the case for dual fueling results in a reduced average temperature at the  
275 end of the compression stroke. This will lead to an overall lower combustion  
276 temperature. With the formation of  $\text{NO}_X$  highly dependent on the thermal  
277 mechanism, the reduced temperature leads to a level of reduced  $\text{NO}_X$ . As  
278 the combustion of the homogeneous mixture propagates from a number of  
279 multi-site ignitions, the increased specific heat capacity will lead to a further  
280 reduction of combustion temperature. Reduction in specific  $\text{NO}_X$  is more  
281 significant at lower power where this reduction ranges between 40%-53%. At  
282 lower powers, the engine is running relatively cooler compared to at higher

Figure 9: Specific heat at constant pressure,  $C_P/R$  as a function of temperature for air and methane

Figure 10: Enthalpy fraction of natural gas during diesel piloted natural gas dual fueling.  
 283 powers and hence the higher heat capacity has a more pronounced effect on  
 284 specific  $NO_X$ .

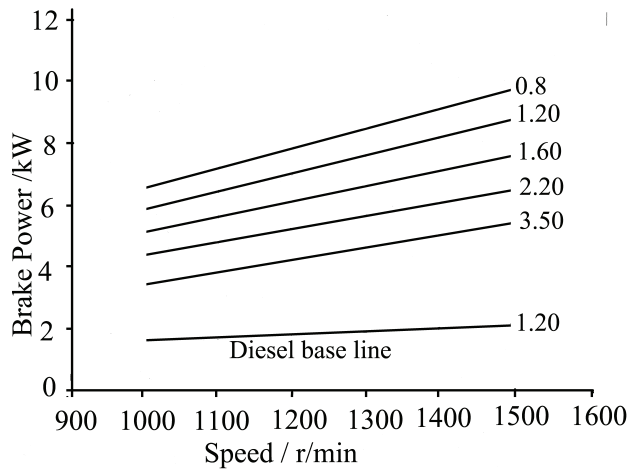

285 As is to be expected, as the power output is increased at a constant speed,  
 286 the absolute  $NO_X$  emissions increase due to the increasing in-cylinder tem-  
 287 peratures, however Figs. 8(a) and 8(b) show specific  $NO_X$  emissions across  
 288 the engine's operational range. For diesel single fueling, as the power output  
 289 increases the  $NO_X$  levels do not increase at the same rate, hence the specific  
 290  $NO_X$  at the higher powers is actually lower. The peak specific  $NO_X$  emis-  
 291 sions are centered around low power and low speed conditions. In terms of  
 292  $NO_X$  emissions, this region is where the engine's combustion temperature  
 293 and power relationship is at its worst.

#### 294 4.1.3. Specific HC

295 Fig. 11(a) presents an experimentally obtained map showing lines of con-  
 296 stant specific HC for diesel based single fueling whereas Fig. 11(b) presents  
 297 a similar map for diesel piloted dual fueling of natural gas.

(a) Specific HC /g/MJ- Diesel

(b) Specific HC/ g/MJ - Diesel Plus NG

Figure 11: Experimentally obtained specific HC contours for diesel single fueling (a) and diesel piloted natural gas dual fueling (b)

298        There is a significant increase in the specific HC emissions at lower and  
 299 medium power outputs for diesel piloted natural gas dual fueling (Fig. 11(b))  
 300 compared to diesel single fueling (Fig. 11(a)). The HC emission iso-contour  
 301 maps reflects that a significant amount of unburnt natural gas is going into

302 the engine exhaust. One possible explanation for this inefficient burning  
303 may be poor flame propagation throughout the homogeneous natural gas-air  
304 mixture.

305 The equivalence ratio ( $\phi$ ) threshold for dual fuel modes is 0.4. Below  
306 this threshold value, the HC emissions increase whereas increasing  $\phi$  beyond  
307 this value results in a decrease in HC emissions. The equivalence ratio in  
308 this case ranges between 0.44 and 0.79 and this is reflected in gradual de-  
309 crease of HC emissions as the load increases. When natural gas contributes  
310 approximately 45% of the total enthalpy (Fig. 10) the specific HC emissions  
311 increase by about 800%. As the load is increased, the difference between the  
312 two modes (single and dual fuel modes) in terms of specific HC emissions  
313 is narrowed down. At maximum load conditions when natural gas enthalpy  
314 fraction is more than 60%, the dual fuel case produces 250% more specific  
315 HC emissions when compared to the diesel single fueling which reflects a  
316 percentage decrease of about 20% when compared to the case when natural  
317 gas contributed about 45% of the total enthalpy required. These higher HC  
318 numbers in dual fueling case can again be attributed to deteriorated com-  
319 bustion (especially in the pre-mixed phase) due to low temperature of the  
320 in-cylinder mixture as explained in the  $\text{NO}_x$  section.

#### 321 4.1.4. Specific $\text{CO}_2$

322 Fig. 12(a) presents an experimentally obtained map showing lines of con-  
323 stant specific  $\text{CO}_2$  for diesel based single fueling whereas Fig. 12(b) presents  
324 a similar map for diesel piloted dual fueling of natural gas. Diesel piloted nat-  
325 ural gas dual fueling produces less  $\text{CO}_2$  emissions.  $\text{CO}_2$  emissions decreases  
326 by 23-30% when diesel is substituted by diesel plus natural gas dual fuel.

(a) Specific CO<sub>2</sub> /g/MJ - Diesel

(b) Specific CO<sub>2</sub> /g/MJ - Diesel Plus NG

Figure 12: Experimentally obtained specific CO<sub>2</sub> contours for diesel single fueling (a) and diesel piloted natural gas dual fueling (b)

327 This decrease in CO<sub>2</sub> can be attributed to lower carbon to hydrogen ratio in  
 328 case of dual fueling. Stoichiometrically, one gram of methane produces 2.0 g  
 329 of CO<sub>2</sub> as compared to 3.2 g produced by 1.0 g of diesel (37.5% difference)

330 *4.2. RME Plus NG*

331 Maps for thermal efficiency, volumetric efficiency, specific  $\text{NO}_x$ , specific  
332 HC and specific  $\text{CO}_2$  have been presented for RME based single fueling and  
333 RME piloted dual fueling of natural gas.

334 *4.2.1. Thermal and volumetric Efficiency*

335 Enthalpy contribution of natural gas in an RME piloted dual fueling of the  
336 natural gas across different operating conditions has been shown in Fig. 13).  
337 It ranges between 48% at relatively lower loads to and 65% at the highest  
338 loads across different speeds( Fig. 14(a) presents an experimentally obtained  
339 map showing iso-contours of thermal efficiency for RME based single fueling  
340 whereas Fig. 14(b) presents a similar map for RME piloted dual fueling  
341 of natural gas. RME piloted dual fueling exhibits slightly inferior thermal  
342 efficiency at lower and medium loads when compared to the single fueling  
343 case (Fig. 14(b)). When compared to RME based single fueling operation  
344 (Fig. 14(a)), the RME piloted dual fueling of natural gas shows a decreases of  
345 13%, 5% and 1.5% in thermal efficiency when the enthalpy fraction (Fig. 13)  
346 of natural gas was 48%, 53% and 58% respectively.

347 No significant difference in thermal efficiency is observed when the natural  
348 gas enthalpy fraction was 60% or above. As discussed in section 4.1.1, this is  
349 believed to be an effect of the pilot fuel failing to ignite and sustain acceptable  
350 combustion in the overall lean homogeneous mixture of natural gas and air.  
351 As with the diesel piloted dual fueling, this argument is supported by the  
352 HC emissions for dual fueling (Fig. 11(b)) which decrease significantly with  
353 increasing power output.

Figure 13: Enthalpy fraction of natural gas during RME piloted natural gas dual fueling.

354 Fig. 15(a) presents an experimentally obtained map showing lines of con-  
 355 stant constant volumetric efficiency for RME based single fueling whereas  
 356 Fig. 15(b) presents a similar map for RME piloted dual fueling of natural gas.  
 357 The volumetric efficiency map (Fig. 15(b)) reflects the lower values for dual  
 358 fuel mode. As with the case for diesel piloted dual fueling as discussed in sec-  
 359 tion 4.1.1 this trend is to be expected as a portion of the inducted air is being  
 360 displaced by the natural gas in the intake. The value and slope of the con-  
 361 stant volumetric efficiency lines for RME piloted dual fuel mode (Fig. 15(b))  
 362 differ slightly from those for diesel piloted dual fuel mode Fig. 7(b). This can  
 363 be attributed to the slightly lower heating value of RME compared to diesel.  
 364 This leads to a larger portion of the total enthalpy in the cylinder coming  
 365 from the natural gas, meaning a larger portion of the intake air is displaced  
 366 by the natural gas.

(a) Thermal Efficiency - RME

(b) Thermal Efficiency - RME Plus NG

Figure 14: Experimentally obtained thermal efficiency contours of RME single fueling (a) and RME piloted natural gas dual fueling (b)

367 4.2.2. Specific  $NO_x$

368 Fig. 16(a) presents an experimentally obtained map showing iso-contours  
 369 of specific  $NO_x$  for RME based single fueling whereas Fig. 16(b) presents a  
 370 similar map for RME piloted dual fueling of natural gas. When compared

(a) Volumetric Efficiency - RME

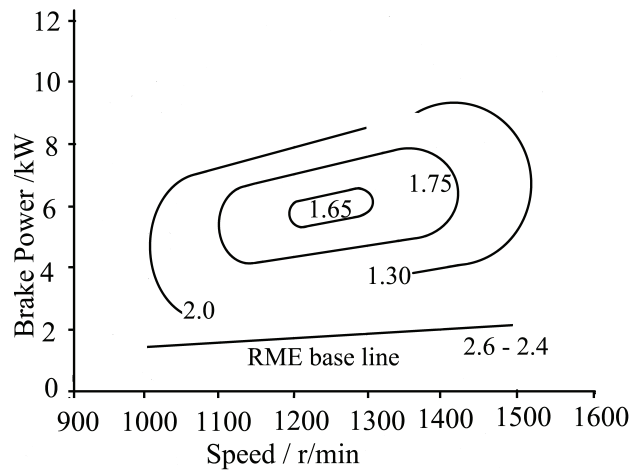

(b) Volumetric Efficiency - RME Plus NG

Figure 15: Experimentally obtained volumetric efficiency contours of RME single fueling (a) and RME piloted natural gas dual fueling (b)

371 to RME based single fueling, the RME based dual fueling results in over-  
 372 all lower specific  $\text{NO}_X$ . This observation holds very good for all range of  
 373 speed and load combinations. Quantitatively, the difference between specific  
 374  $\text{NO}_X$  is the lowest at the the junction of higher loads and medium speeds

(a) Specific  $\text{NO}_X$  /g/MJ - RME

(b) Specific  $\text{NO}_X$  /g/MJ - RME Plus NG

Figure 16: Experimentally obtained specific  $\text{NO}_X$  contours for RME single fueling (a) and RME piloted natural gas dual fueling (b)

375 where it is approximately 7%. At medium loads and medium speeds, the  
 376 specific  $\text{NO}_X$  in dual fueling mode are reduced by approximately 40%. At  
 377 higher speeds for all range of load, the specific  $\text{NO}_X$  reduction ranges be-  
 378 tween 40-43%. Another interesting observation is the variation in location of

(a) Specific HC /g/MJ - RME

(b) Specific HC /g/MJ- RME Plus NG

Figure 17: Experimentally obtained specific HC contours for RME single fueling (a) and RME piloted natural gas dual fueling (b)

379 the maximum specific  $\text{NO}_X$ . While operating in single fuel mode, the maxi-  
 380 mum specific  $\text{NO}_X$  are approximately concentrated at the junction of medium  
 381 loads and medium speeds. This holds good both for diesel (Fig. 8(a)) as well  
 382 as RME (Fig. 16(a)). Moving outwards from the position of maximum  $\text{NO}_X$

(a) Specific CO<sub>2</sub> /g/MJ - RME

(b) Specific CO<sub>2</sub> /g/MJ - RME Plus NG

Figure 18: Experimentally obtained specific CO<sub>2</sub> contours for RME single fueling (a) and RME piloted natural gas dual fueling (b)

383 results in gradual decrease in specific NO<sub>X</sub> numbers. On the other hand,  
 384 the specific NO<sub>X</sub> contours for the two dual fueling cases reflect an opposite  
 385 trend. Medium load and medium speed combination carries the lowest spe-  
 386 cific NO<sub>X</sub> and a gradual increase in specific NO<sub>X</sub> is observed on all outward

387 contours. The only exception to this trend are the specific  $\text{NO}_X$  contours  
388 at higher speeds. The specific  $\text{NO}_X$  maps both for diesel (Fig. 8(b)) and  
389 RME (Fig. 16(b)) piloted dual fueling case reflect that the latter produces  
390 slightly higher specific  $\text{NO}_X$  as compared to the former. This difference in  
391 specific  $\text{NO}_X$  numbers for the two dual fueling cases can be explained by rel-  
392 atively higher absolute  $\text{NO}_X$  numbers in case of RME and a slight variation  
393 in thermal efficiency (Figs 6(b) and 14(b)).

#### 394 4.2.3. Specific HC

395 Fig. 17(a) presents an experimentally obtained map showing lines of con-  
396 stant specific HC for RME based single fueling whereas Fig. 17(b) presents a  
397 similar map for RME piloted dual fueling of natural gas. When compared to  
398 RME based single fueling case, the RME piloted combustion of natural gas  
399 results in higher specific HC emissions. So far as the comparison of these two  
400 modes involving RME is concerned, the explanation put forward in specific  
401 HC section (section 4.1.3) of diesel piloted combustion of natural gas holds  
402 for RME piloted combustion of natural gas as well. When the two dual fuel-  
403 ing cases are concerned, there is no significant difference in HC values when  
404 RME substitutes diesel as pilot fuel for natural gas combustion in CI engines.  
405 When compared to the diesel piloted dual fueling of natural gas (Fig. 11(a)),  
406 a slight reduction in HC values at higher loads when RME pilots the natural  
407 gas combustion can be attributed to higher equivalence ratio at these condi-  
408 tions. This higher equivalence ratio is caused by extra in-fuel oxygen in case  
409 of RME. At lower and medium loads, RME led combustion of natural gas  
410 has resulted in higher specific HC emissions. This may be attributed to the  
411 argument proposed in section 4.1.1 with the pilot fuel unable to ignite and

412 sustain acceptable combustion in an overall lean mixture in the cylinder.

#### 413 4.2.4. Specific CO<sub>2</sub>

414 Fig. 18(a) presents an experimentally obtained map showing lines of con-  
415 stant specific CO<sub>2</sub> for RME based single fueling whereas Fig. 18(b) presents  
416 a similar map for RME piloted dual fueling of natural gas. As with the  
417 diesel piloted dual fueling natural gas (Fig. 18(b)), RME piloted dual fueling  
418 results in lower specific CO<sub>2</sub> emissions (Fig. 18(b)) compared to the RME  
419 based single fueling (Fig. 18(b)). The difference can attributed be to the  
420 reduction in carbon going into the engine in case of dual fueling with nat-  
421 ural gas. The data used to plot these maps has been used to tabulate the  
422 performance comparison of the two pilot fuels in Table 2

## 423 5. Conclusion

424 Performance and emissions data have been collected at 6 engine operating  
425 speeds and 8 different load settings for single fueling, and 6 load settings for  
426 dual fueling. The load settings have been used to determine the brake power  
427 the engine is producing. Iso-contours of thermal efficiency, specific NO<sub>x</sub>,  
428 specific HC and specific CO<sub>2</sub> have been traced on a power-speed plots using  
429 the data collected. The maps therefore represent operation of the engine over  
430 its full speed and power range. It is shown that data collected and presented  
431 in this manner highlights aspects of engine operation which may be missed  
432 by more conventional engine testing techniques at limited speed and power  
433 ranges. The performance of two pilot fuels, diesel and RME, have been  
434 examined using these full engine maps. Contrary to most of the most studies  
435 presenting performance and emissions characteristics of compression-ignition

Pilot Fuel	Natural Gas Enthalpy Fraction	Thermal Efficiency %ge change	Specific HC %ge change	Specific CO <sub>2</sub> %ge change
Diesel	45%	13.79%↓	875%↑	17.5%↓
	50%	6.45%↓	730%↑	9.3%↓
	55%	3.22%↓	635%↑	11.9%↓
	60%	3.03%↓	600%↑	12.2%↓
	64%	6.25%↑	266%↑	12.5%↓

Table 2: Performance comparison of Diesel and RME as pilot fuels in natural gas combustion

436 (CI) engines operating with various fuels, including natural gas, this work has  
437 presented experimentally investigated, assessed, compared, and discussed the  
438 performance and emissions contours of a natural gas fueled CI engine with  
439 two pilot fuels (diesel and RME).

- 440 • Apart from the highest power outputs, the natural gas dual fueling  
441 case was less efficient as compared to the respective pilot fuel based  
442 single fueling. These efficiency losses at lower powers can be attributed  
443 to the under-utilization of the pilot fuel. The lower thermal efficiency  
444 values at lower power may be attributed to the failure of pilot fuel to  
445 ignite and sustain adequate combustion of the natural gas-air mixture.  
446 Whilst the local equivalence ratio in the region of the pilot injection may

447 be near unity (stoichiometric), especially during the initial pre-mixed  
448 combustion phase, there can exist some areas with in the combustion  
449 chamber away from the pilot region where there is a lean homogeneous  
450 mixture of natural gas and air. This argument is supported by relatively  
451 lower Fuel to air ratio obtained in case of dual fueling. As the power  
452 output increases the dual fuel mode recovers the thermal efficiency  
453 losses suffered at the lower power outputs with the dual fuel mode  
454 exhibiting slightly higher F/A ratios at these conditions.

- 455 • In dual fuel mode the maximum thermal efficiency reached with RME  
456 is marginally lower than the maximum thermal efficiency reached with  
457 diesel.
- 458 • The slope of the constant volumetric efficiency is flatter for natural  
459 gas dual fueling with diesel than for baseline diesel operation and the  
460 values are lower. This is a consequence of the method used to introduce  
461 natural gas into the engine. As the natural gas has been introduced  
462 via manifold injection, a portion of the intake air is displaced by the  
463 natural gas, reducing the measured volume flow rate of air into the  
464 engine. This leads to a reduction of the engine's volumetric flow rate.  
465 The slope of the constant volumetric efficiency lines differs due to a  
466 change in the scaling of volumetric efficiency with engine speed. As the  
467 amount of natural gas added is increased to meet the increase in speed  
468 demand, larger amounts of air are displaced. As the natural gas is  
469 introduced at the manifold and does not flow through the entire intake  
470 system but the air does, the scaling law as noted by Heywood [22] does

471

not hold well.

472

473

474

475

476

477

478

479

480

481

482

- Natural gas based dual fueling has resulted in significant reduction in  $\text{NO}_x$  when compared to the diesel and RME based single fueling cases. This reduction in  $\text{NO}_x$  is a direct consequence of difference in the in-cylinder mixture composition prior to ignition and combustion events. Significantly higher specific heat capacity of natural gas raises the overall specific heat capacity of the mixture and results in lower temperatures during compression stroke. Also the presence of natural gas affect the peak in-cylinder (adiabatic) temperature. With the formation of  $\text{NO}_x$  highly dependent on thermal mechanism, the lower in-cylinder temperature results in lower specific  $\text{NO}_x$  as compared to the single fueling.

483

484

485

486

487

488

- Specific  $\text{NO}_x$  emissions in case of both single fueling cases are centered in the middle of the map and they decrease in all direction from this region of maximum specific  $\text{NO}_x$ . On the other hand , an opposite trend is observed with natural gas dual fueling where minimum specific  $\text{NO}_x$  are centered at the middle of the map and they increase in all directions from this region of minimum  $\text{NO}_x$ .

489

490

491

492

493

494

- At lower power outputs across all speeds, the specific HC emissions were significantly higher in case of dual fueling when compared to the respective pilot fuel based single fueling. This can be attributed to low in-cylinder temperature due to relatively higher specific heat capacity of the mixture. As the power was increased at constant speed, the specific HC emissions were significantly reduced, though still higher than the

495        respective single fueling cases. Also, the equivalence ratio threshold for  
496        dual fuel modes is 0.4. Below this threshold value, the HC emissions  
497        increase whereas increasing equivalence ratio beyond this value results  
498        in a decrease in HC emissions. The equivalence ratio in this case ranges  
499        between 0.44 and 0.79 and this is reflected in gradual decrease of HC  
500        emissions as the load increase.

- 501        • Studying the specific  $\text{NO}_X$  and specific HC maps together has revealed  
502        that the of junction of lower powers and lower speeds is a region in the  
503        maps where the engine shows the worst trade-off between the  $\text{NO}_X$  and  
504        HC emissions as the two emissions are higher in this region.

593 **List of Figures**

594 1 Experimental rig of dual-fueled CI engine . . . . . 10  
 595 2 Experimentally obtained in-cylinder pressure (a) and rate of  
 596 energy release (b) for for diesel and RME at a BMEP of 0.125  
 597 MPa and 1000 rev/min . . . . . 12  
 598 3 Experimentally obtained in-cylinder pressure (a) and rate of  
 599 energy release (b) for diesel and RME at a BMEP of 0.503  
 600 MPa and 1000 rev/min . . . . . 12  
 601 4 Experimentally obtained in-cylinder pressure (a) and rate of  
 602 energy release (b) for pure diesel and diesel piloted natural gas  
 603 at 0.503 MPa with diesel pilot set at 0.125 MPa for the dual  
 604 fueling case 1000 rev/min . . . . . 13  
 605 5 Experimentally obtained in-cylinder pressure (a) and rate of  
 606 energy release (b) for pure RME and RME piloted natural gas  
 607 at 0.503 MPa with diesel pilot set at 0.125 MPa for the dual  
 608 fueling case 1000 rev/min . . . . . 13
